4.12.4.3.1.2. Two new families: **PIF/Harbinger** *and* **Transib** *PIF/Harbinger* and *Transib* are two newly discovered families of DNA transposons in insects. *PIF* and related TEs *Harbinger* and *Tc8* have previously been found in plants and nematodes (Kapitonov and Jurka, 1999; Le *et al*., 2001; Zhang *et al*., 2001) and they may have mobilized *Tourist*, one of the most abundant MITEs in plants (Zhang *et al*., 2001; Jiang *et al*., 2003). Analysis of the *A. gambiae* genome uncovered approximately 30 families of *PIF/Harbinger*-like transposons, although the majority of them are "fossil"-like sequences (Biedler *et al*., unpublished data). Like all other *PIF/Harbinger*-like transposons, the *A. gambiae PIF/Harbinger*-like elements are characterized by 3 bp TSDs and transposase sequences similar to that of the bacterial *IS5* elements (Zhang *et al*., 2001). A second new family, the *Transib* transposons, are so far found only in *D. melanogster* and *A. gambiae* (Kapitonov and Jurka, 2003b). They use a unique transposase and generate 5 bp TSDs. *Transib* transposons have resided in these two genomes for a long time as extensive *in silico* reconstruction had to be employed to trace back the ancestral full-length copies (Kapitonov and Jurka, 2003b).

Figure 7 Phylogenetic analysis of diverse non-LTR retrotransposons found in *Anopheles gambiae*. Phylogenetic analysis classifies 104 families of *A. gambiae* elements into two new clades and eight previously defined clades. The two new clades, *Loner* and *Outcast*, are in bold. Shown here is the neighbor-joining tree constructed using alignment of approximately 260 amino acids of the reverse transcriptase (RT) domain from non-LTR retrotransposons of *A. gambiae* and representative elements in different clades. The tree was rooted using RTs of three prokaryotic Group II introns (not shown). Maximum parsimony was also used which produced a similar phylogenetic tree (not shown). Confidence of the groupings was estimated using 500 bootstrap replications for both methods. The first and second numbers at a particular node represent the bootstrap values derived from 500 neighbor-joining and maximum parsimony analysis, respectively. Only the values for the major groupings (clades) that are above 50% are shown. The scale at bottom left indicates amino acid divergence. The names of elements from previously established clades are given but names of new *A. gambiae* non-LTR families are omitted to save space (see Biedler and Tu, 2003). Previously reported *A. gambiae* non-LTRs in the tree are *Q*, *T1*, *RT1*, and *RT2* (Besansky, 1990; Besansky *et al*., 1992, 1994). (Reproduced with permission from Biedler, J., Tu, Z., **2003**. Non-LTR retrotransposons in the African malaria mosquito, *Anopheles gambiae*: unprecedented diversity and evidence of recent activity. *Mol. Biol. Evol. 20*, 1811–1825; © Oxford University Press.)

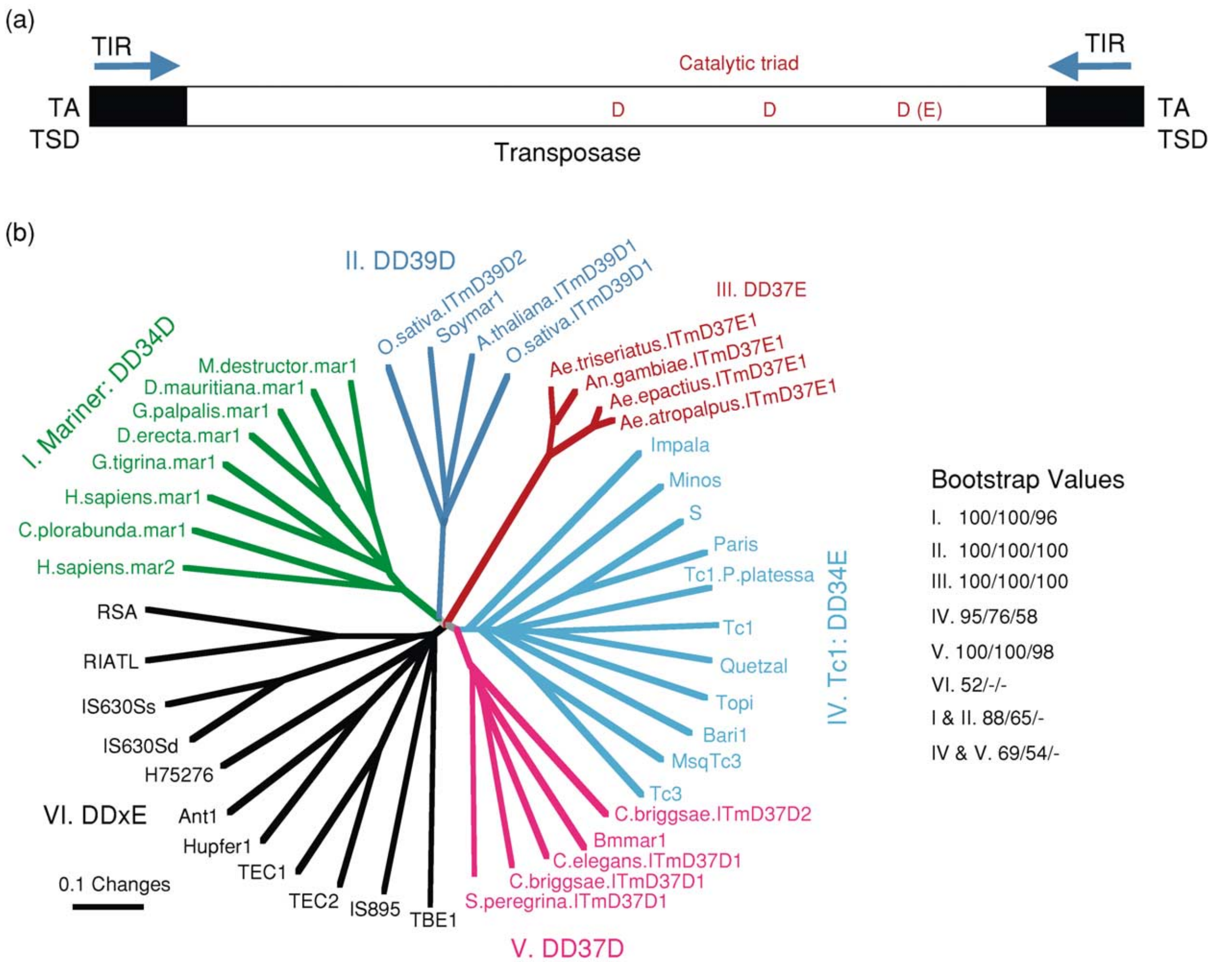

Figure 8 Structural features and classification of the *IS630-Tc1-mariner* superfamily. (a) Structural features. The catalytic triad in the transposase is highlighted. The characteristic TA target site duplications (TSDs) flanking an *IS630-Tc1-mariner* are shown. The terminal inverted repeats (TIRs) specify the boundries of the element. Possible introns are not shown. (b) Phylogenetic relationship between members of the *IS630-Tc1-mariner* superfamily on the basis of the catalytic domain. The alignment used here was previously described (Shao and Tu, 2001). The tree shown here is an unrooted phylogram constructed using a minimum evolution algorithm. Two additional methods, neighbor-joining and maximum parsimony, were also used. Confidence of the groupings was estimated using 500 bootstrap replications. The bootstrap value represents percent of times that branches were grouped together at a particular node. The first, second, and third numbers represent the bootstrap value derived from minimum evolution, neighbor-joining, and maximum parsimony analysis, respectively. Only the values for major groupings are shown. Various colors indicate different clades. All phylogenetic analyses were conducted using PAUP 4.0 b8 (Swofford, 2001). Note that a recently described group of transposons that contain a DD41D catalytic triad was not included here. They are a distinct group related to the DD37D transoposons (Gomulski *et al*., 2001). (Modified from Shao, H., Tu, Z., **2001**. Expanding the diversity of the *IS630-Tc1-mariner* superfamily: discovery of a unique DD37E transposon and reclassification of the DD37D and DD39D transposons. *Genetics 159*, 1103–1115.)

4.12.4.3.2. MITEs As shown in Table 2, MITEs that share similar TSDs and TIRs with DNA transposons in the *IS630-Tc1-mariner, hAT, piggyBac, PIF/Harbinger* families have been found in three species of mosquitoes. A MITE that generates a specific TA TSD has also been reported in a coleopteran (Braquart *et al*., 1999). Two *hAT*-like MITEs have been recently found in *D. willistoni* (Holyoake and Kidwell, 2003) and a deletion-derivative of the *pogo* transposon has been found in *D. melanogaster* (Feschotte *et al*., 2002).

The relationship between *PIF/Harbinger*-like DNA transposons and related *Tourist*-like MITEs in *A. gambiae* is interesting (Biedler *et al*., unpublished data). There are multiple *PIF/Harbinger*-like DNA transposon families in *A. gambiae*, all of which have the characteristic AT-rich 3 bp TSDs. Although the TIRs are highly conserved between different copies of a family, they are often variable between different *PIF/Harbinger*-like transposon families. Only two MITE families were found to be apparent deletion derivatives of two *PIF/Harbinger*-like

transposons (**Figure 4**). On the other hand, 20 families of the *Tourist*-like MITEs were found to share similar TSDs and TIRs with their respective *PIF/Harbinger*-like transposons although no similarities were found between the internal sequences of these MITEs and any of the *PIF/Harbinger*-like transposons. The implication of these results on the evolution of MITEs is discussed elsewhere (see Sections 4.12.2 and 4.12.6).

4.12.4.3.2.1.* m9bp*, MITEs with 9 bp TSDs Two novel groups of MITEs have been discovered in *Aedes aegypti*. One group, *m9bp*, includes two families of putative MITEs that have 9 bp TSDs (Mao and Tu, unpublished data). These two families are moderately repetitive and evidence of insertion has been found for both families. Several plant MITEs have 9 bp TSDs (Charrier *et al*., 1999; Feschotte *et al*., 2002) and they may be mobilized by *Mutator*-like transposons only found in plants (Walbot and Rudenko, 2002). The discovery of 9 bp TSD MITEs in *Aedes aegypti* is the first in animals, which may indicate a broader distribution of the *Mutator*-like transposons.

4.12.4.3.2.2.* m7bp*, MITEs with 7 bp TSDs Three families of putative MITEs that have 7 bp TSDs (*m7bp_1, m7bp_2, m7bp_3*) have been found in *Aedes aegypti* (Mao and Tu, unpublished data). These families are moderately repetitive and evidence of insertion has been found for all three families. These 7 bp TSD MITEs could potentially lead to the discovery of an entirely new family of eukaryotic DNA transposons, as 7 bp TSD elements have until now only been found in bacteria (Krebs *et al*., 1990; Mahillon and Chandler, 1998). No full-length protein-encoding DNA transposons that produce 7 bp TSDs have been identified in *A. aegypti* yet. However, this is within expectation considering the fragmented nature of the BAC-end sequences in the current *Aedes aegypti* database.

4.12.4.3.2.3.* Microuli*, a miniature subterminal inverted-repeat TE *Microuli* is a family of small (~200 bp) and highly AT rich (68.8–72.6%) TEs found in *Aedes aegypti* that do not have any coding capacity (Tu and Orphanidis, 2001). There is a 61 to 62 bp internal subterminal inverted repeat as well as a 7 bp subterminal inverted repeat 11 bp from the two termini. In addition, there are three imperfect subterminal direct repeats near the 5′ end. All of the above characteristics clearly resemble the structural features of MITEs. The only feature that separates *Microuli* from MITEs is that *Microuli* elements lack TIRs. Therefore, we use the phrase "miniature subterminal inverted-repeat transposable elements," or MSITEs, to refer to the structural characteristics of the *Microuli* elements. Short insertion sequences that contain subterminal inverted repeats but lack TIRs have been identified in the genomes of rice and a *Culex* mosquito (Song *et al*., 1998; Feschotte and Mouches, 2000a). Fourteen of the 19 nucleotides at the 5′ (and only 5′) terminus of *Microuli* are identical to the TIR of *Wuneng*, a previously characterized MITE in *Aedes aegypti* (Tu, 1997). Both *Microuli* and *Wuneng* insert specifically into the TTAA target. It has been suggested that MITEs and the autonomous DNA transposons share the same transposition machinery based on common TIRs (Feschotte *et al*., 2002). Then how did *Microuli* transpose without the TIRs? The three subterminal direct repeats could potentially be the binding sites for transposases because subterminal inverted repeats and subterminal direct repeats have been shown to bind transposases in several autonomous DNA transposons (Morgan and Middleton, 1990; Beall and Rio, 1997; Becker and Kunze, 1997). It remains unclear how the termini of *Microuli* are determined at the strand cleavage step without the TIR. The TTAA target duplication plus a 3 bp TIR are essential for the excision of the autonomous transposon *piggyBac* (Bauser *et al*., 1999). Therefore, it is possible that *Microuli* may also be able to use the TTAA target sequence as part of the signal for recombination. It is tempting to hypothesize that some MITEs could evolve from MSITEs through mutation and/or recombination events at the termini which would result in TIRs.

4.12.4.3.3. *Helitrons* *Helitrons* have been found in *D. melanogaster* and *Anopheles gambiae*, which use a rolling-circle mechanism of transposition (Kapitonov and Jurka, 2001; Kapitonov and Jurka, 2003b) (**Table 2**). Insect *Helitrons* has several characteristics including short specific terminal sequences (5′ TC and 3′ CTAG), a 3′ hairpin, and the lack of TSDs. Instead of a cut-and-paste transposase, *Helitron1* in *A. gambiae* encodes an intronless protein including domains similar to helicase and replication initiation protein. There are approximately 100 copies of *Helitron* elements in *A. gambiae* that form 10 distinct families (Kapitonov and Jurka, 2003b).

In summary, the diversity demonstrated by insect TEs encompasses all classes and types of eukaryotic elements. Analyses of insect TEs have more than once led to discoveries that broadly impacted the field of TE research. Because of extensive genetic studies, *D. melanogaster* has long served as the launching pad for the discovery of novel families

of TEs in eukaryotes. The advent of genomics has provided the opportunity for the discovery of novel TEs in a wide range of organisms including non-drosophilid insects. As demonstrated above, greater TE diversity may be revealed and new insights may be gained from these genomic analyses.

4.12.5. Search for Active TEs in Insects

Active TEs may be used as tools for genetic manipulation of insects in basic and applied research (see Section 4.12.9). In addition, the behavior of TEs in host genomes and their spread in natural populations may be studied by monitoring active TE families. It is therefore highly desirable to isolate active copies of TEs. As described above (see Section 4.12.3), TEs discovered from observations of genetic mutations tend to result from active transposition events. Although several active TEs were discovered in this manner, this discovery process relies heavily on fortuitous events. Several methods that, when used in concert, could provide a systematic approach to uncover active TEs in insect genomes are described below.

4.12.5.1. Identification of Potentially Active TEs on the Basis of Bioinformatics Analysis

As discussed above, the ongoing genome revolution has produced an immense amount of sequence data from which diverse TEs can be identified in various insect genomes. The computational programs described above (see Section 4.12.3) can greatly facilitate the discovery and characterization of a large number of TE families. Unfortunately, the vast majority of TEs have accumulated inactivating mutations during evolution, rendering the discovery of active TEs the difficult task of “finding needles in a haystack.” Bioinformatics analysis can provide leads to potentially active candidates that can be studied further. For example, using a semi-automated reiterative search strategy, many potentially active families of non-LTR retrotransposons in the *A. gambiae* genome were identified (Biedler and Tu, 2003). Here candidate families were identified based on sequence characteristics, which include the presence of full-length elements, intact ORFs, multiple copies with high nucleotide identity, and the presence of TSDs. High nucleotide identity indicates recent amplification from a source element, without enough time for divergence caused by nucleotide substitution and other mutations. It should be emphasized that sequence analysis can only provide leads for further analysis. For example, high sequence identity between copies of a TE family may not always indicate recent transposition activity because it can also result from gene conversion events.

4.12.5.2. Detection of TE Transcription

Transcription is a required step during transposition of the RNA-mediated TEs. Although DNA-mediated TEs do not use RNA as an intermediate, transcription is required for production of transposase proteins. Therefore, the detection of transcription may offer further support for an active family in both classes of TEs. Transcription can be inferred if a match was found in an expressed sequence tag (EST) database to a TE sequence from the same organism. For example, 21 families of non-LTR retrotransposons had significant hits when BLAST searches were carried out against over 94 000 *A. gambiae* ESTs downloaded from NCBI (Biedler and Tu, 2003). Transcription of TEs can also be detected experimentally by real time polymerase chain reaction (RT-PCR), Northern blot, and even microarray. The source of mRNA may affect the outcome of these experiments because the activity of some TEs may be temporally and spatially controlled. It has been shown that TE activity can be elevated during the culturing of mammalian and plant cells (Wessler, 1996; Grandbastien, 1998; Liu and Wendel, 2000; Kazazian and Goodier, 2002). Different cell lines are available for a number of insect species. One caveat of the above approach is that, transcripts shown by either experimental detection or EST analysis could arise from spurious transcription. These transcripts could originate by transcription from a nearby host promoter.

4.12.5.3. Detection of Transposition Events by TE Display

TE display (Van den Broeck *et al*., 1998; Casa *et al*., 2000; Biedler *et al*., 2003) is a sensentive and reproducible experimental method to detect TE insertions. We have used it recently to study insertion site polymorphisms of endogenous insect TEs (Biedler *et al*., 2003) (see Sections 4.12.7 and 4.12.9). It is a modified form of amplified fragment length polymorphism (AFLP), the difference being that one primer is designed according to a TE sequence (**Figure 9**). First, genomic DNA is digested using a four-base restriction enzyme such as BfaI and then ligated to an adapter sequence. This is followed by two rounds of PCR. During the second PCR, a radioactive-labeled nested primer specific for the TE sequence is used following a touch-down protocol. After the second PCR, products are run on a sequencing gel and visualized by autoradiography. TE display is a powerful tool for genome-wide analysis of TE insertions and for detection of new insertions due to transposition (De Keukeleire *et al*.,

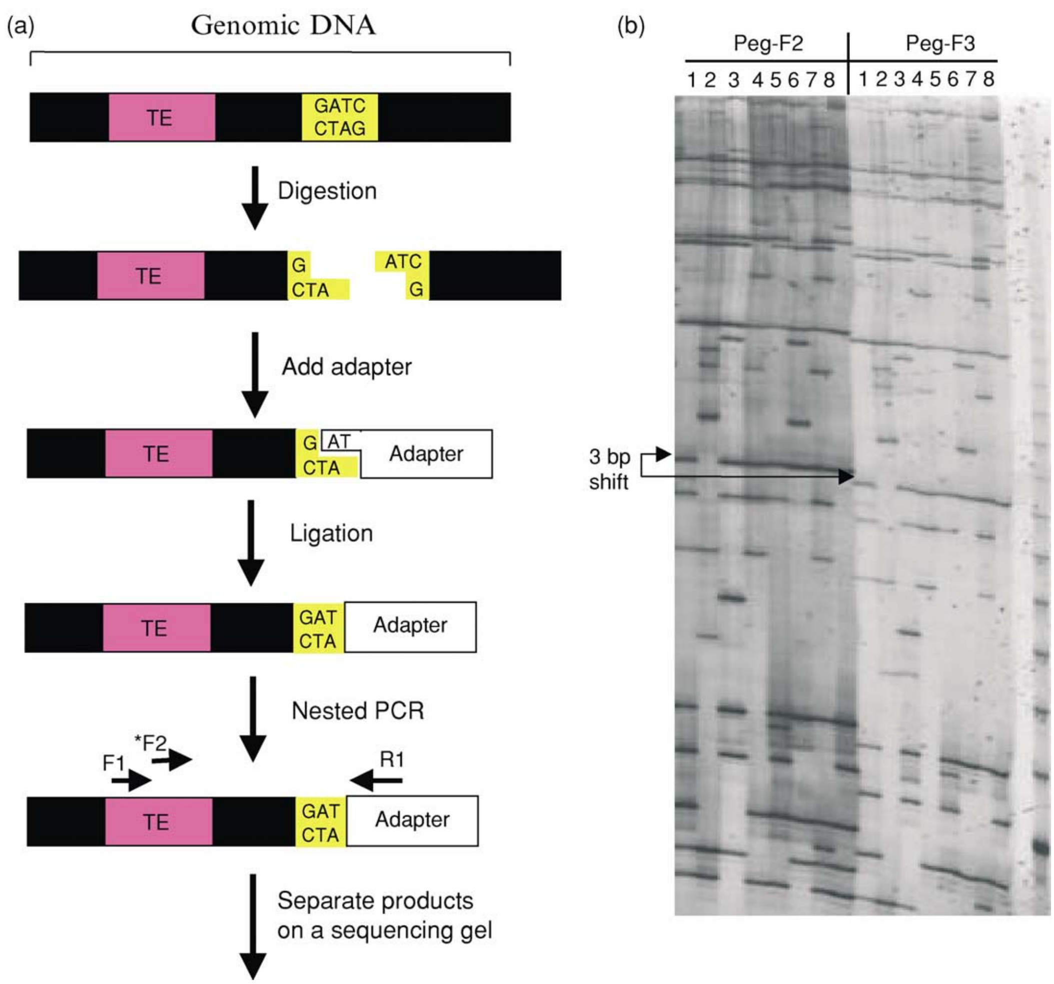

Figure 9 TE display, a method to scan multiple insertion sites of a TE in the genome. (a) Principle of TE display, which is a modified form of amplified fragment length polymorphism (AFLP). The difference is that TE-specific primers (F1 and F2) are used in addition to the adaptor primer (R1). F2 is labeled as shown by the asterisk. (b) Partial image of a TE display using primers for the *Pegasus* element with eight female individuals from an *Anopheles gambiae* colony (GAMCAM) originally collected from Cameroon (Biedler *et al.*, 2003). The eight samples on the left are amplified with a *Pegasus*-specific primer Peg-F2. The eight samples on the right are the same as those on the left except they were amplified with primer Peg-F3, which is designed to amplify a product smaller by three bases. The three base shift is clearly observable. A 10 bp ladder is shown on the right. Bands from a TE display gel were reamplified and sequenced, showing that they contained *Pegasus* sequences as well as flanking genomic and adapter sequences in the expected order (not shown). Comigrating bands among different individuals had the same flanking genomic sequence, indicating that they were from the same genomic locus. TE displays have been also developed using two highly reiterated SINEs, *SINE200* in *A. gambiae* and *Feilai* in *Aedes aegypti* (not shown). (Modified from Biedler, J., Qi, Y., Holligan, D., Della Torre, A., Wessler, S., *et al.*, **2003**. Transposable element (TE) display and rapid detection of TE insertion polymorphism in the *Anopheles gambiae* species complex. *Insect Mol. Biol. 12*, 211–216.)

2001). It offers a higher degree of sensitivity and resolution than genomic Southern blot analysis.

TE display has been used to detect somatic cell transposition (De Keukeleire *et al.*, 2001), simply by looking for the presence of new bands that represent newly transposed copies of a TE. A caveat of this approach is that a change in a restriction site may also result in new TE display bands. The same method may also be used to identify germline transposition by comparing TE display patterns of parent insects with the patterns of a large number of offspring. Alternatively, one could take advantage of the possibility that some TEs are activated in cell culture. Using TE display, one may be able to identify active families by comparing the relative abundance of a TE in cultured cells with that in individuals from different strains of the same species (Jiang *et al.*, 2003). This approach is based on the assumption that some TE families may be more active in cultured cells than in live organisms.

After TE display, one side of the new insertional copy and its associated flanking sequence can be recovered because the band can be reamplified and sequenced. To recover the entire sequence of the

newly inserted copy, one has to rely on mapping the insertion site to the genome if the genome sequence is available. Otherwise, further PCR or screening of a genomic library is necessary to recover the entire copy and both sides of the flanking sequence. The identified insertional copy itself may or may not be active because it could have been mobilized by a *trans*-acting protein that is encoded by an active TE in the genome. However, the experiment described above can demonstrate *in vivo* or *ex vivo* transposition events and the recovered insertional copy may lead to the identification of the autonomous active TE on the basis of shared *cis*-acting sequences such as TIRs.

4.12.5.4. Detection of Transposition Events by Inverse PCR

Actively transposing DNA-mediated TEs can be identified as extrachromsomal DNA in the form of linear or circular intermediates or byproducts (Arca *et al.*, 1997; Gorbunova and Levy, 1997) (see **Chapter 4.13**). Using a set of outward-orienting primers within the TE, the circular extrachromosomal copies may be amplified, which could serve as evidence of active excision or transposition. However, head-to-head copies of the same TE in the genome could also produce PCR products when outward-orienting primers are used, which must be ruled out by sequencing and further analysis. Extrachromosomal circles of *Hermes* (see **Chapter 4.13**) and *Pegasus* (Coy and Tu, unpublished data) have been identified. Imprecise excision had occurred when *Pegasus* is excised from its genomic location within the *A. gambiae* genome.

4.12.5.5. Transposition Assay, Reconstruction, and Genetic Screen

Transposition assays can be used to directly assess the functionalities of both the *cis*-(TIRs) and the *trans*- (transposase) components of a DNA transposon, allowing the demonstration of autonomous transposition events (see **Chapter 4.13**). In addition, transposition assays have also been established for the detection of retrotransposition of non-LTR retrotransposons (Jensen *et al.*, 1994; Ostertag *et al.*, 2000). Recently, a molecular reconstruction approach has been developed to restore inactivated copies of a vertebrate transposon, *Sleeping Beauty* (Ivics *et al.*, 1997), but such an approach requires extensive phylogenetic analysis and elaborate reconstructions (Ivics *et al.*, 1997). As an alternative, a genetic screen based on a bacterial system has been developed to identify hyperactive copies of an insect *mariner* transposon among randomly mutated copies (Lampe *et al.*, 1999). This approach can potentially be used to screen for active copies of transposons that do not require specific host factors. In summary, the progress in insect genome projects and the development and application of the methods described in this section will greatly facilitate searches for active TEs. The task of "finding needles in a haystack" could potentially be replaced by targeted and more efficient investigations.

4.12.6. Evolution of Insect TEs

The evolutionary dynamics of TEs are complex, which is in part due to their replication and their interactions with the host genome. The intricate dynamics between TEs and their host genomes are further complicated by the ability of some TEs to cross species barriers and spread in a new genome by horizontal transfer. Horizontal transfer may be an important part of the life cycle of some TEs and contribute to their continued success during evolution (Silva *et al.*, 2004). While the broad distribution of both RNA-mediated TEs and DNA-mediated TEs in all eukaryotic groups is evidence of the long-term evolutionary success of TEs, the two TE classes may have adopted different strategies, for which several insect TEs in both classes provide good examples.

4.12.6.1. Genomic Considerations of TE Evolution

It has been hypothesized that TE insertions may present three types of potentially deleterious effects including: (1) insertional mutagenesis which may disrupt gene function and/or regulation; (2) transcriptional/translational cost of the production of TE transcripts and proteins; and (3) ectopic recombination between homologous copies of TEs in different chromosomal locations that may result in duplication, deletion, and a new linkage relationship between genes (Nuzhdin, 1999; Bartolome *et al.*, 2002; Kidwell and Lisch, 2002; Rizzon *et al.*, 2002; Petrov *et al.*, 2003). The costs of having TEs may also include the cost associated with DNA replication when TEs occupy a large fraction of the genome. Obviously, these hypotheses are not mutually exclusive. This section discusses the intragenomic dynamics of TE–host interaction. The population dynamics affecting the spread of TEs in insects, which is also important for TE evolution, will be discussed below (see Section 4.12.7).

4.12.6.1.1. Self-regulation of insect TEs Both TE-driven mechanisms (self-regulation) and host-driven mechanisms (host control) have been shown to affect TE activities in insects. Self-regulation has been shown for *mariner* and *P* elements in *Drosophila*

(Hartl *et al.*, 1997; Kidwell and Lisch, 2001). In the case of the *Drosophila P* element, self-regulation is achieved through the activities of at least two types of element-encoded repressors. In the case of *mariner*, several mechanisms may be involved including overproduction inhibition (an increase in the amount of transposase results in a decrease in net transposase activity), missense mutation effects (defective transposase encoded by missense copies interfering with functional transposase), and titration effects by inactive copies. In this regard, it is interesting to note that several hyperactive mutants of an active *mariner*, originally discovered in the horn fly, have been isolated (Lampe *et al.*, 1999). This suggests that the horn fly *mariner* has not evolved for maximal activity.

4.12.6.1.2. Host control of TEs in insects Host control of TE activity can either be targeted at a particular family of TEs or a large group of TEs in general. Family-specific host control has been demonstrated in several cases (Labrador and Corces, 2002). The best example so far is the control of *gypsy* activity by a genetic locus *flamenco* in *D. melanogaster* (Bucheton, 1995). Homozygous female mutants of *flamenco*, which is an X-linked recessive gene that represses the transposition of *gypsy*, produce progeny that show high rates of *gypsy* transposition. The relief of the suppression of *gypsy* activity in *flamenco* mutants, which are also called permissive mutants, functions through maternal factors. Another example of host control is the *P* element which only transposes in the germline because correct splicing of the *P* transcript only occurs in germ cells. The tissue-specificity of the *P* element allows it to transmit efficiently to the next generation while minimizing potential damage to the host. Two host genes have been implicated in the inhibition of *P* activity in somatic cells (Siebel *et al.*, 1992, 1995).

RNA interference (RNAi), a mechanism that confers posttranscriptional degradation of mRNA on the basis of homology to small fragments of double-stranded RNA, has been implicated as a host defense mechanism against a broad spectrum of TEs in the nematode *Caenorhabditis elegans* (Ketting *et al.*, 1999; Tabara *et al.*, 1999). RNAi has shown to function in *Drosophila* and a few other insects as well (Misquitta *et al.*, 1999; Hammond *et al.*, 2000). The potential role of RNAi as a general control method against TE activity in *Drosophila* has recently been proposed on the basis of cosuppression of the *I* element by an increasing number of *I*-related transgenes (Jensen *et al.*, 1999; Labrador and Corces, 2002). It has been proposed that RNAi has evolved as a host defense mechanism against the invasion by TEs and viruses (review: Fedoroff, 2002). In addition to posttranscriptional degradation, this defense system may also be involved in the formation of transcriptionally inactive heterochromatin where TEs and other repeats concentrate (Couzin, 2002).

4.12.6.1.3. Nonrandom distribution of insect TEs Patterns of nonrandom TE distribution have been shown in both *D. melanogaster* and *A. gambiae* (Bartolome *et al.*, 2002; Holt *et al.*, 2002; Kapitonov and Jurka, 2003b). TEs tend to accumulate in heterochromatin. Such a distribution bias could result either from preferential TE insertion, or selection against insertions in euchromatic regions, or both. Bartolome and colleagues suggested that the abundance of TEs is more strongly associated with local recombination rates (Bartolome *et al.*, 2002), which are low in heterochromatic regions, rather than with gene density. They argue that this association is consistent with the hypothesis that selection against harmful effects of ectopic recombination is a major force opposing TE spread. However, selection against insertional mutagenesis is also at work as shown by the absence of insertions in coding regions. The insertional bias of *P* elements has been demonstrated recently during genome-scale *P* mutagenesis analysis (Spradling *et al.*, 1995, 1999). Therefore insertion bias may contribute to the biased pattern of TE distribution in insects. A related topic here is the suggestion that concentrations of TE insertions in the *Drosophila* Y chromosome may have contributed to the evolutionary process leading to its inactivation (Labrador and Corces, 2002). It should be noted that not all TEs have a bias towards heterochromatic or recombination-deprived regions. On the basis of analysis of limited gene sequences, it was shown that *Aedes aegypti* MITEs tend to be associated with the noncoding regions within or near genes (Tu, 1997), which is similar to what has been observed for plant MITEs (Zhang *et al.*, 2000).

4.12.6.1.4. Autonomous and nonautonomous TEs In addition to the genomic interactions described above (see Section 4.12.6.1.3), most TEs have to contend with the fact that defective copies are often generated during or after transposition. This process could contribute to self-regulation as discussed above (see Section 4.12.6.1.1). It can also lead to total inactivation and ultimate extinction of a TE as the inactive TE population eventually overwhelms the active copies (Eickbush and Malik, 2002). Therefore, the replicative ability that is responsible for the success of the TE may also lead

to its inactivation in a genome. Interestingly, some nonautonomous TEs have been very successful with regard to amplification, although the mechanisms that contribute to their success are not entirely clear. For example, SINEs found in insect genomes including *Aedes aegypti*, *Anopheles gambiae*, and *Bombyx mori* (**Table 1**) all contain thousands of copies. Similarly, most of the MITEs found in insects are also highly reiterated although low-copy-number families are also found (Tu, 1997, 2000, 2001a). The small size of MITEs and SINEs may confer less deleterious effects on the host, either because they are less efficient substrates for homologous recombination (Petrov *et al*., 2003) or because their impact on neighboring genes may be less severe. Therefore reduced selection pressure as well as other properties inherent to MITEs and SINEs could contribute to their apparent success. It is a fascinating question as to how SINEs and MITEs affect the evolution of the autonomous TEs that mobilize them.

4.12.6.2. Vertical Transmission and Horizontal Transfer of Insect TEs

As described above (see Section 4.12.6.1), the replicative ability that is responsible for the success of a TE may in some cases lead to its inactivation by generating defective copies or by activating host control mechanisms. This is especially true for DNA transposons. Therefore, the ability to escape the above vertical inactivation by invading a new genome would greatly enhance the evolutionary success of DNA transposons. However, not all TEs have adopted this life cycle of invasion, amplification, senescence, and new invasion (Hartl *et al*., 1997; Eickbush and Malik, 2002; Robertson, 2002) (Figure 10).

4.12.6.2.1. Detection of horizontal transfer The occurrence of horizontal transfer can be supported in various degrees by three types of evidence (Silva *et al*., 2004). First, detection of elements with a high level of sequence similarity in divergent taxa will offer strong support for horizontal transfer although variable rates of sequence change should be considered. Second, detection of phylogenetic incongruence between TEs and their hosts will also provide relatively strong support for horizontal transfer. However, this alone will not be convincing, especially in light of the high levels of intragenomic diversity of TE families observed in insects. In other words, the existence of multiple TE lineages could confound the phylogenetic analysis as paralogous lineages may be treated as orthologous ones. Finally, horizontal transfer may be inferred when "patchy" distribution of a TE among closely related taxa is observed. This type of support is weak as loss of

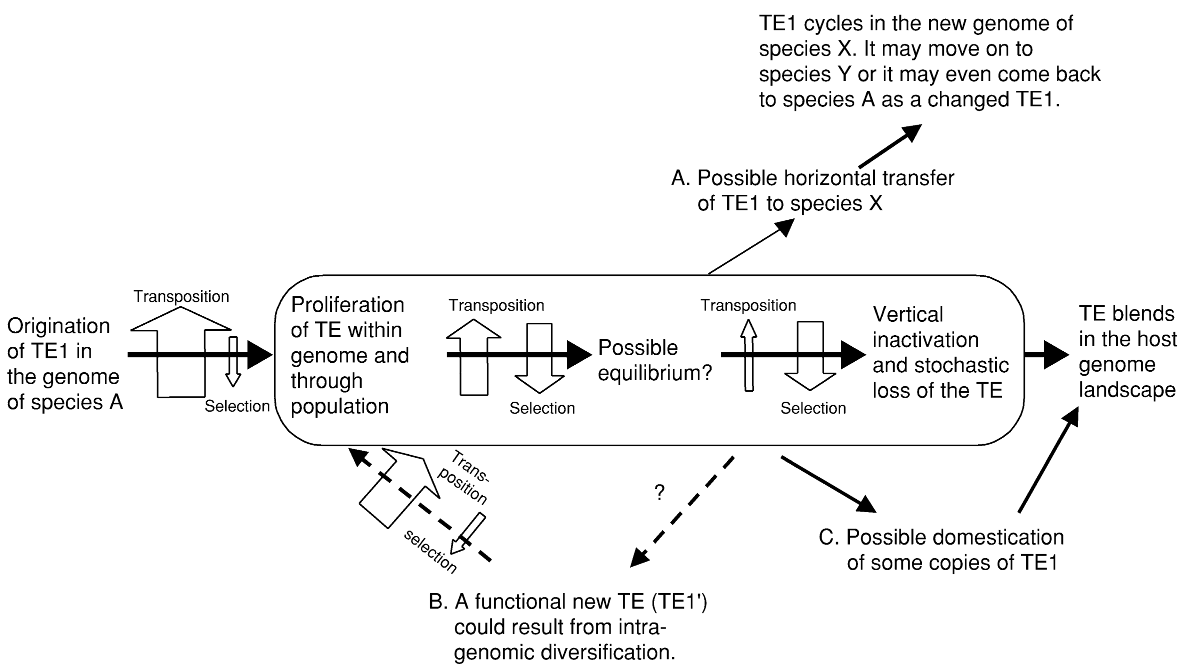

Figure 10 A model of the evolutionary dynamics of TEs in eukaryotic genomes. This hypothetical model incorporates recent work by several groups (Hartl *et al*., 1997; Lampe *et al*., 2001; Silva *et al*., 2004). Some aspects of this model are better suited for DNA transposons that generally have a high propensity for horizontal transfer. Three possible alternatives to inactivation and stochostic loss are highlighted (A, B, and C).

TEs from sister taxa may result from a phenomenon similar to assortment of an ancestral polymorphism (Silva *et al.*, 2004).

4.12.6.2.2. Horizontal transfer and vertical transmission in insects: differences between different groups of TEs The first case of eukaryotic horizontal transfer was reported in *Drosophila*, where the *P* element was shown to have invaded the *D. melanogaster* genome during the last century from a species in the *D. willistoni* group (review: Kidwell, 1992). Evidence for this lateral event includes all three types of support described above and is therefore widely accepted (Silva *et al.*, 2004). Further analyses of a large number of *P* element sequences from a number of *Drosophila* species showed that many horizontal transfer events must have occurred to account for the current distribution pattern of *P* in *Drosophila* (Silva and Kidwell, 2000; Silva *et al.*, 2004). Another spectacular case of horizontal transfer, which was also initially discovered in insects, involves the *mariner* transposons. The *mariner* transposon family has been implicated in hundreds or more horizontal transfer events among a wide range of animal species including a large number of insects across different orders (Robertson, 1993, 2002). It has been shown that the newly discovered *ITmD37E* transposons have also been involved in relatively frequent horizontal transfer events among different mosquito species (Shao and Tu, 2001, unpublished data). Finally, horizontal transfers of *hobo* and *piggyBac* has been shown in flies and moths (Bonnivard *et al.*, 2000; Handler and McCombs, 2000). It has been proposed that horizontal transfer may be a key link in the life cycle of those DNA TEs that are not intricately associated with their host biology, allowing them to escape the vertical inactivation and stochastic loss (Hartl *et al.*, 1997). Thus, these types of TEs may be regarded as "resident aliens" in a host (Plasterk *et al.*, 1999). It has been shown that selection of some *mariner* transposases acts only during horizontal transfer, which is consistent with the invasion–inactivation–escape model (Lampe *et al.*, 2003).

Horizontal transfer has also been shown for LTR retrotransposons in insects. A clear example involves the *copia* element in *Drosophila* (Jordan *et al.*, 1999). The *copia* elements in *D. melanogaster* and *D. willistoni*, two divergent species that separated more than 40 million years ago, showed less than 1% nucleotide difference. It appears that *copia* jumped from *D. melanogaster* to *D. willistoni*. Horizontal transfer of the *Drosophila gypsy* element has also been reported (Terzian *et al.*, 2000; Vazquez-Manrique *et al.*, 2000).

Possible horizontal transfer of the *Drosophila* non-LTR retrotransposon *Jockey* was suggested on the basis of phylogenetic incongruence (Mizrokhi and Mazo, 1990). However, Malik and colleagues recently showed that an analysis that takes into account the rates of evolution was consistent with vertical transmission of the *Jockey* elements in *Drosophila* (Malik *et al.*, 1999). Eickbush and Malik further suggest that no convincing evidence exists for the horizontal transfer of any non-LTR retrotransposon during the past 600 million years (Eickbush and Malik, 2002). In addition, strict vertical transmission of two non-LTR retrotransposons *R1* and *R2* have been shown in *Drosophila* (Eickbush and Eickbush, 1995). In these cases, the TE phylogenies well reflect those of the host species. Furthermore, it was shown that the relationship between *R2* elements from several insect orders including Diptera, Lepidoptera, Coleoptera, and Hymenoptera is consistent with vertical transmission (Eickbush, 2002).

4.12.6.2.3. Possible reasons for differing propensities for horizontal transfer Two reasons have been proposed to explain the apparent differences in the prevalence of horizontal transfer events between DNA transposons and non-LTR retrotransposons (Eickbush and Malik, 2002). The first is that DNA transposons need horizontal transfer for their long-term survival but non-LTR retrotransposons appear not to be dependent on such rare evolutionary events. Defective copies of DNA transposons retain the ability to be transposed as long as they have the *cis*-acting signals such as the TIRs. This indiscrimination leads to the inevitable fate of inactivation of the entire transposon family. Therefore, horizontal transfer offers a much-needed escape from the above vertical inactivation, which greatly enhances the evolutionary success of DNA transposons. On the other hand, it has been shown that the RT of non-LTR retrotransposons tends to associate with the mRNA molecules from which they were translated (Wei *et al.*, 2001). This *cis*-preference would bias transposition events in favor of the active elements, thus providing a mechanism to sustain the non-LTR retrotransposons. However, the *cis*-preference is not enough to prevent the highly successful retrotransposition of SINEs in insects (Adams *et al.*, 1986; Tu, 1999) and other organisms (Lander *et al.*, 2001), which presumably borrows the retrotransposition machinery from non-LTR retrotransposons. It will be interesting to see how SINEs affect the evolution of their

non-LTR retrotransposon "partners." The second explanation is that DNA transposons may be more predisposed to horizontal transfer than non-LTR retrotransposons. The transposition process of DNA transposons involves an extrachromosomal DNA intermediate, which may facilitate horizontal transfer (Eickbush and Malik, 2002) (see Section 4.12.6.2.4). DNA transposons use their transposase for integration, which may be less dependent on host repair machinery than non-LTR retrotransposons and thus not as restricted to its original host.

LTR retrotransposons form an extrachromosomal DNA intermediate and use transposase-like IN for integration. Therefore, LTR retrotransposons have access to the same horizontal transfer mechanisms as the DNA transposons although their life cycle may not require horizontal transfer because defective copies are not thought to be a major factor (Eickbush and Malik, 2002). It should be noted that the above are general statements and that the propensity for horizontal transfer may vary among individual families within the three groups discussed here.

4.12.6.2.4. Mechanisms of horizontal transfer Mechanisms of horizontal transfer are poorly understood although direct transfer of the extrachromosomal DNA intermediate and indirect transfer through a viral vector have been proposed as possible mechanisms (Eickbush and Malik, 2002; Silva *et al*., 2004). Geographical and temporal overlap between the donor and recipient host species may be essential. An intriguing case of horizontal transfer of a *mariner* element between a parasitoid wasp and its lepidopteran host offers a good example of such overlap (Yoshiyama *et al*., 2001).

4.12.6.3. Other Possible Evolutionary Strategies

In addition to horizontal transfer and vertical extinction, recent studies suggest that there might be a third way, or an alternative strategy, which may be adopted by some TEs (Lampe *et al*., 2001). On the basis of the loss of interaction between *mariner* transposons of slightly changed TIRs, it was proposed that intraspecific or intragenomic diversification of *mariner* transposons may allow the newly diverged *mariner* to start a new lineage. Although this requires the coevolutionary events to occur in both the transposase and the TIRs, this scenario would provide the transposon the opportunity to escape vertical inactivation because it is now virtually a brand new element in a virgin genome because of the loss of interaction between itself and its relatives in the genome. Genome sequencing has provided increasing opportunity to survey the diversity of different families of TEs. Our recent analysis showed a large number of lineages of non-LTR retrotransposons of the *CR1* and *Jockey* clades in *A. gambiae* (Biedler and Tu, 2003) (**Figure 7**). Given the presence of multiple recently active lineages within the *CR1* and *Jockey* clades, it is tempting to speculate that the observed diversity may be driven by competition among different non-LTR families or by attempts to escape suppressive mechanisms imposed by the host.

On the other hand, some TEs are recruited for host functions and thus become "domesticated" (Lander *et al*., 2001; Kidwell and Lisch, 2002). This type of molecular domestication is the ultimate case of trading "freedom" for "security." It allows TEs to sustain and positively impact the host, examples of which will be discussed below (see Section 4.12.8). Strictly speaking, these domesticated TEs are no longer TEs. However, it is theoretically possible that these "domesticated" TEs could revert back to their "old ways" on rare occasions.

4.12.6.4. Understanding the Intragenomic Diversity of Insect TEs

High levels of TE diversity have been reported in the two insect genomes in which large-scale systematic analyses have been carried out (Holt *et al*., 2002; Kaminker *et al*., 2002; Kapitonov and Jurka, 2003b; Biedler and Tu, 2003) (**Figures 4** and **7**). The evolutionary process that generated this diversity may also be quite diverse. It is possible that the evolution of some TEs may be a complex mix of both vertical transmission and horizontal transfer events. Parsing out the results of intragenomic diversification from those of horizontal transfer events may require additional data from related species. Understanding the process responsible for the intragenomic diversity of insect TEs and the potential interactions between different TE families in insect genomes will be both challenging and rewarding. A summary of the current hypothesis on TE evolution is illustrated in **Figure 10**. Some aspects of this model are better suited for DNA transposons that have a high propensity for horizontal transfer.

4.12.7. TEs in Insect Populations

4.12.7.1. Fundamental Questions and Practical Relevance

In general, the increase of TE copy number through transposition is balanced by selective forces against the potential genetic load of TEs on host fitness (Nuzhdin, 1999). The control of transposition rate of TEs and other mechanisms to minimize their deleterious effects has been discussed (see Section 4.12.6). The population dynamics affecting the

spread of TEs in insect genomes is described. Earlier work on TEs in *Drosophila* populations suggest that the copy numbers in euchromatic regions are low and most euchromatic copies exist at very low frequency (<5%) in the population (Petrov *et al.*, 2003). This is interpreted as evidence of selection against individual TE copies in nature. It has been hypothesized that this selection is against three types of potentially overlapping deleterious effects by TEs including insertional mutagenesis, transcriptional or translational cost, and ectopic recombinations between similar copies of TEs in different chromosomal regions (Nuzhdin, 1999; Bartolome *et al.*, 2002; Kidwell and Lisch, 2002; Petrov *et al.*, 2003). One of the major questions in this field has been parsing out the main factors containing the spread of TEs in natural populations. From an applied perspective, TEs have been proposed as tools to genetically drive the spread of beneficial genes through insect populations to control infectious diseases (e.g., Ashburner *et al.*, 1998; Alphey *et al.*, 2002). For such a sophisticated approach to work, it is important to understand the population dynamics of TEs in their insect hosts.

4.12.7.2. Experimental Approaches

In situ hybridization of the *Drosophila* polytene chromosomes has been the main workhorse in studies of the population dynamics of different TE families (Charlesworth and Langley, 1989). Although extremely useful, this method obviously only works in species with accessible polytene chromosomes and it is not efficient in detecting short regions of sequence similarities to the probe (Petrov *et al.*, 2003). An alternative method, genomic Southern blotting, was also used to study TE insertions and excisions in *Drosophila* (Maside *et al.*, 2001). Although Southern blotting is a good method to estimate TE copy numbers, it is not reliable when the numbers are high. In addition, it may not be able to detect low-frequency sites in cases where multiple small insects have to be pooled to obtain enough high-quality genomic DNA. However, a single *Drosophila* can provide enough DNA for a Southern blot experiment.

TE display, a genome-scale detection method for TE insertions (see Section 4.12.5.3), has been used recently in *Drosophila* and two sibling species of mosquitoes *A. gambiae* and *A. arabiensis* (Biedler *et al.*, 2003; Yang and Nuzhdin, 2003). Because it is a PCR-based method, TE display allows investigation of multiple TE families using genomic DNA isolated from an individual insect. Although extremely powerful, this method cannot reliably distinguish homozygous from heterozygous insertions. However, TE display will allow recovery of a specific insertion site by sequencing the corresponding band. The sequence flanking the TE copy can be used to locate the specific site by searching the genome database if available or by inverse PCR. Therefore, sequences flanking a TE at a specific locus can be used as primers to amplify genomic DNA isolated from an individual sample (**Figure 11**). When the PCR products are run on an agarose gel, individuals with insertions at both alleles will show a single high molecular mass band while individuals with no insertions at either allele will give a single low molecular mass band (**Figure 11**). Individuals that have heterozygous alleles will yield both bands. Thus this locus-specific approach is codominant. When the genome sequence or a bulk of genomic sequences are available for an insect species, it is not absolutely necessary to couple locus-specific PCR with TE display because a number of TE insertion sites will already have been available for analysis (Petrov *et al.*, 2003). However, TE display can facilitate the investigation by providing a rapid scan of a large number of loci and by providing initial assessment of the level of polymorphism.

4.12.7.3. Recent Advances

Population studies, mainly of *Drosophila* TEs, suggest that selection against ectopic recombination may be the major factor in containing TE copy number in nature (Bartolome *et al.*, 2002; Kidwell and Lisch, 2002; Rizzon *et al.*, 2002; Petrov *et al.*, 2003). However, this issue apparently is quite complex (Biemont *et al.*, 1997). Although there appears to be evidence rejecting the effect of TE expression as a selection mechanism (Yang and Nuzhdin, 2003), the relative importance of insertional mutagenesis as a force to contain TE spread in *Drosophila* populations is still debated (Biemont *et al.*, 1997; Bartolome *et al.*, 2002; Petrov *et al.*, 2003).

TE insertions were shown to be generally at very low frequencies in natural populations of *D. melanogaster* (Charlesworth and Langley, 1989), which is consistent with the hypothesis of natural selection acting against the TE copies. However, recent surveys in *D. melanogaster* revealed an unexpected number of sites that are either fixed or of high frequency (Petrov *et al.*, 2003; Yang and Nuzhdin, 2003). In addition, an analysis of a retrotransposon *Osvaldo* in *D. buzzatii* (Labrador *et al.*, 1998) has shown a number of euchromatic sites with high occupancy in all populations from the Iberian Peninsula. The authors suggest that genetic drift is

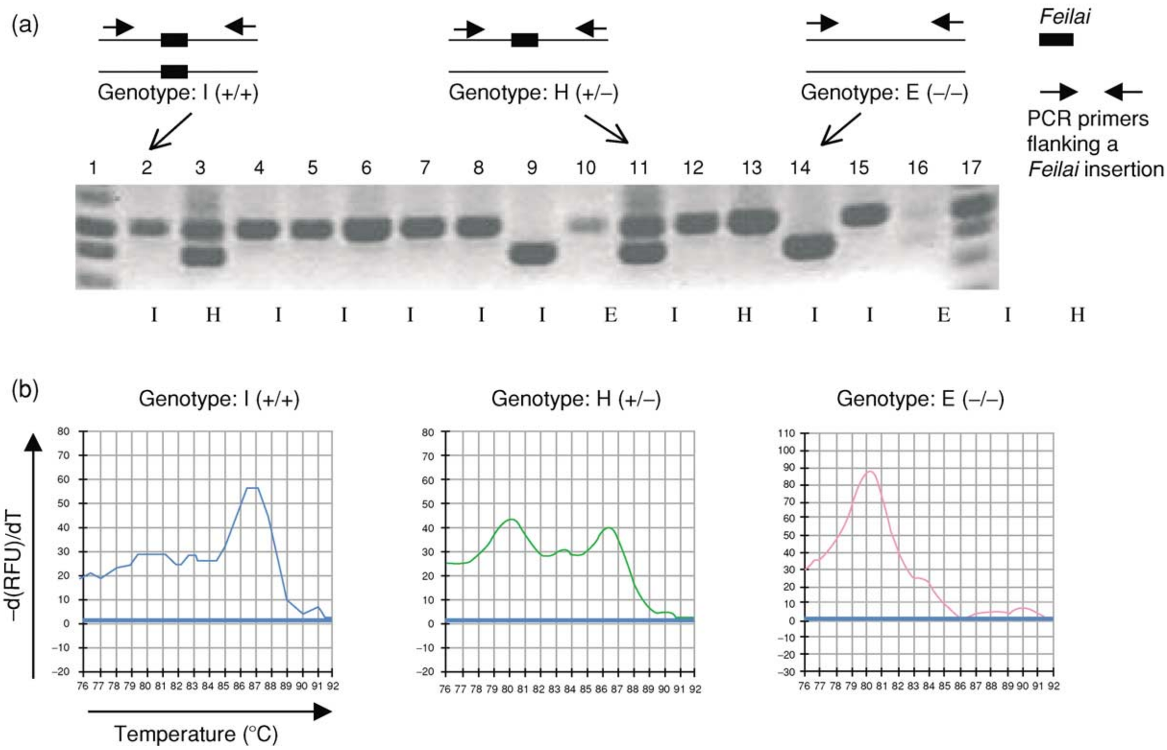

Figure 11 Locus-specific PCR for the detection of SINE insertion polymorphism. Shown here are images from analysis of a *Feilai* insertion in the yellow fever mosquito, *Aedes aegypti*. (a) Different genotypes revealed by PCR and agarose gel electrophoresis. Lanes 1 and 17 are size markers. Lanes 2–16 are PCR products from 15 individual mosquitoes collected in Thailand. Three genotypes and their corresponding banding patterns are shown. I, homozygous insertion (+/+); E, homozygous empty (−/−); H, heterozygotes (+/−). (b) The same three genotypes at the same *Feilai* insertion site detected using melt-curve analysis on an iCycler from Bio-Rad (Hercules, CA). The peaks represent PCR products. Higher melting temperature reflect larger and/or GC-rich PCR products. −d(RFU)/dT represents the rate of change of the relative fluorescence units (RFU) with time (T).

the main force responsible for the high frequency distribution of *Osvaldo* as a result of the founder effect. Using TE display, it has been found that fixed and high-occupancy sites of MITEs and SINEs are common in *A. gambiae* and *Aedes aegypti* strains and natural populations (Qi and Tu, unpublished data). The small size of MITEs and SINEs may confer less deleterious effects on the host either because they are less efficient substrates for ectopic recombination (Petrov *et al.*, 2003) or because their impact on neighboring genes may be less severe. Further analyses of different types of TEs in the natural populations of a wide range of insects will allow us to examine the validity and applicability of some of the fundamental conclusions drawn from the analysis of *Drosophila* TEs. The use of TE display and the advent of insect genomics provide an exciting opportunity for such investigations.

It may be reasonable to assume that TE copy number and insertion frequency in a population are highly dynamic parameters that can be influenced by TE-specific factors such as their intrinsic ability for transposition and self-regulation, by species- or genome-specific factors such as deletion and recombination rate and genomic control of transposition, and of course by effective population size and other ecological factors. As most population surveys only reflect a cross-section during evolution, the relative stage of a TE in its life cycle (**Figure 10**) is also an important consideration (Vieira *et al.*, 1999).

4.12.8. Impact of TEs in Insects

4.12.8.1. TEs and Genome Size and Organization

TEs are integral and significant components of eukaryotic genomes (Berg and Howe, 1989; Sherratt, 1995; Kidwell and Lisch, 2000; Craig *et al.*, 2002). For example, at least 46% of the human genome is TE-derived sequences (Lander *et al.*, 2001). In the two "completed" insect genomes, TEs occupy approximately 22% in *D. melanogaster* (Kapitonov and Jurka, 2003b) and at least 16% of the euchromatic region in *Anopheles gambiae* (Holt *et al.*, 2002). It has been proposed that the differing TE abundance may account for the "C value

paradox," which reflects the discrepancy between genome size or DNA content of an organism (as indicated by the C value) and its biological complexity (Kidwell, 2002). In other words, organisms with similar genetic/biological complexity may have huge variations in genome size due to differences in TE content. In higher eukaryotes, the interspersed repetitive sequences such as TEs are often organized in two distinct patterns relative to single copy DNA. One pattern of organization is the "short period interspersion" where single copy DNA is often interrupted every 1–3 kb by repetitive elements (Davidson *et al.*, 1975). The other is the "long period interspersion" in which single copy DNA in the euchromatic region is less interrupted by repetitive sequences (Davidson *et al.*, 1975). These two different patterns are probably shaped by the diversity, varied distribution, and abundance of repetitive sequences in the genome.

As noted above, TEs occupy approximately 22% of the *D. melanogaster* genome, which is threefold higher than previously reported (Kapitonov and Jurka, 2003b). Most TEs in *D. melanogaster* are relatively young (<20 million years old) and they consitute a major component of the paracentromeric regions. Detailed comparisons of TE age, distribution, and abundance are under way between the *D. melanogaster* and the *A. gambiae* genomes. Further comparisons that include other genomes such as *Aedes aegypti*, *Apis mellifera*, and *Bombyx mori* will be extremely informative. Some preliminary information gleaned from a comparative analysis of different species of mosquitoes are briefly described. Genome size and organization vary significantly between different mosquitoes. The genome of *Anopheles gambiae* is 270 Mb in size, and it is organized in a pattern of "long period interspersion" (Rai and Black, 1999). In contrast, the *Aedes aegypti* genome is 800 Mb in size, and it is organized in a pattern of mainly "short period interspersion" (Warren and Crampton, 1991). The relative abundance of MITEs and SINEs in these two mosquito genomes is interesting. The copy number of *Anopheles gambiae* MITEs ranges from 40 to 1340, much lower compared with 400 to 10 000 copies of MITEs in *Aedes aegypti* (Tu, 1997, 2000, 2001a). Similarly, the *Aedes aegypti* SINE family *Feilai* has 60 000 copies while *SINE200* in *Anopheles gambiae* has fewer than 6000 copies (Tu, 1999, unpublished data). The difference in the relative abundance of MITEs and SINEs may have contributed to the different organizations of the mosquito genomes and reflect different types of interactions between the hosts and these widespread TEs. Because of their small size, the copy number differences in MITEs may not explain the bulk of differences in the size of these two mosquito genomes. The relative abundance of other TEs, different deletion rates, simple repeat expansion, and large-segment duplication are among other possible contributing factors (Petrov, 2001). In *Anopheles gambiae*, TEs including MITEs are significantly more concentrated in heterochromatic regions (Holt *et al.*, 2002). Alternatively, indications that a few families of MITEs are associated with the noncoding regions of genes in *Aedes aegypti* are presented (Tu, 1997). It is possible that unlike many other TEs, MITEs may be tolerated in gene-rich euchromatic regions in *A. aegypti*. MITEs have been found near plant genes where they could potentially affect gene regulation and/or define chromatin domains through structures such as matrix attachment regions (Wessler *et al.*, 1995; Tikhonov *et al.*, 2000). Varied amounts of repetitive elements have also been shown to be a major factor for the nearly threefold intraspecific differences of genome size in populations of the Asian tiger mosquito, *A. albopictus* (Rai and Black, 1999). Such an intraspecific variation provides a rare opportunity to study the contribution of TEs to genome evolution at the initial stage of the evolutionary process.

As noted before, TEs can induce chromosomal rearrangements through ectopic recombination and other mechanisms (Gray, 2000). Such rearrangements could result in gross reorganizations of the chromosomes, which may have a significant evolutionary impact as suggested by McClintock (McClintock, 1984). A DNA TE named *Odysseus* was found adjacent to the distal breakpoint of a naturally occurring paracentric chromosomal inversion that is characteristic of *Anopheles arabiensis*, one of the cryptic species in the *A. gambiae* complex (Mathiopoulos *et al.*, 1998). Similar evidence of TE involvement in chromosomal rearrangement has been reported in *Drosophila* (Lim and Simmons, 1994; Caceres *et al.*, 2001).

4.12.8.2. Evolutionary Impact

The tremendous potential for TEs to generate genetic diversity has long been recognized (McClintock, 1956). They can cause spontaneous mutation, recombination, chromosomal rearrangement, and hybrid dysgenesis (Bregliano *et al.*, 1980; Engels, 1989; Shiroishi *et al.*, 1993; Mathiopoulos *et al.*, 1998). However, the long-term evolutionary impact of TEs is less clear. TEs have been generally regarded as "selfish" DNA since the early 1980s (Doolittle and Sapienza, 1980; Orgel and Crick, 1980) as opposed to the original "controlling elements"

hypothesis stating that TEs provide the physical basis controlling gene action and mutation (McClintock, 1956). This change of attitude was mainly due to the realization that TEs are somewhat "independent" genetic units and that their replicative ability allows them to spread even when they are not beneficial to the host organism. The question of whether the "selfish" TEs are just "junk DNA" to the host, or whether they can play important and even adaptive roles in organismal evolution is at the heart of the debate. Thanks in part to recent studies of insect TEs, it is increasingly clear that there may be a middle ground between the "junk DNA" and the "controlling elements" hypotheses. The host genome can be viewed as an ecological community with complex host–TE and TE–TE interactions (Brookfield, 1995; Kidwell and Lisch, 2000). Given the opportunistic nature of the evolutionary process, a "selfish" element could develop a wide spectrum of relationships with their host. They could be a "junk parasite," a "molecular symbiont," or something in between.

TE insertions are often under negative selection and their activities are under tight control by themselves and their host genomes (Bucheton, 1995; Hartl *et al*., 1997; Lin and Avery, 1999). Therefore the mere presence of TEs may represent a powerful genetic force with which the genome has been evolving. The possibility that RNAi has evolved as a host defense mechanism against the invasion by TEs and viruses and the potential involvement of RNAi in the formation of transcriptionally inactive heterochromatin are good examples of the host reacting to TE activities (Couzin, 2002). DNA transposons such as the *P* element in *Drosophila* can induce mutations by insertion as well imprecise excision in the coding or regulatory regions of genes (Kidwell and Lisch, 2002). On a larger scale, TE insertions can serve as substrates for homologous recombination that can result in chromosomal deletion, duplication, and inversion. Polymorphic chromosomal inversions are common in *Drosophila* and *A. gambiae*. TEs are often implicated in the generation of these inversions (Kidwell and Lisch, 2002) (see Section 4.12.8.1). It is proposed that these natural chromosomal inversions may result in reproductive isolation and perhaps genetic changes that allow *A. gambiae* to exploit a range of ecological niches (Mathiopoulos *et al*., 1999).

Recent evidence also indicates that some TEs may be co-opted to contribute to organismal biology. One of the early examples supporting this concept was the discovery that the telomere in *Drosophila* was maintained by site-specific insertions of two retrotransposons *HET-A* and *TART* (Biessmann *et al*., 1992; Levis *et al*., 1993). In addition, some TEs such as MITEs are often found near genes where they may change the expression profile of nearby host genes (Tu, 1997). The recruitment of TE insertions to produce diversity in gene expression profiles may have a better chance to confer a selective advantage when it occurs in duplicated genes. A fascinating genome-wide analysis showed that retrotransposition was responsible for the creation of a significant number of new functional genes in *Drosophila* (Betran *et al*., 2002). Finally, Some TE copies can be "domesticated" and take on a host function (see Section 4.12.6.3). For example, one of the *P* element repeats appears to have evolved the function of transcription factors (Miller *et al*., 1995). Other examples of "domesticated" TEs found in noninsect species include the *RAG1* and *RAG2* genes involved in V(D)J recombination in vertebrate lymphocytes and the more than 40 new genes derived from TEs in the human genome (Kidwell and Lisch, 2000; Lander *et al*., 2001; Gellert, 2002). On the basis of their broad distribution in bacteria, archea, and eukaryotes (Craig *et al*., 2002), it is safe to assume that TEs have long been, and will continue to be, evolving together with the immensely diverse life forms on this planet.

4.12.9. Applications of Insect TEs

4.12.9.1. Endogenous TEs and Genetic Manipulation of Insects

P element-based transgenic and mutagenesis tools in *D. melanogaster* have played a major role in the tremendous success of this tiny fly as a model organism for genetic analysis. A limited number of DNA transposons such as *hobo*, *mariner, minos,* and *piggyBac*, which have a broader host range than *P*, are being developed as tools in insects (see **Chapter 4.13**). Further analysis of TEs in insect genomes may expand the pool of active DNA transposons, which may be used to generate a set of tools with diverse features that can be used collectively for a variety of genetic analysis in different insects. In addition to simply transforming an insect, active TEs mentioned above are used to construct specific vectors to be used in gene trapping, enhancer trapping, and genome-wide insertional mutagenesis studies (Spradling *et al*., 1999; Klinakis *et al*., 2000; Horn *et al*., 2003). These analyses are powerful new ways to investigate gene function and regulation on a genome scale.

In addition to providing new active TEs to be used as tools for genetic manipulations of insects, a better understanding of endogenous TEs will allow

better-informed usage of current transposon-based genetic tools. Interactions between exogenous and endogenous transposons that share similar TIRs have been shown to be a potential problem (Sundararajan *et al.*, 1999; Jasinskiene *et al.*, 2000). Such interactions could be significant in light of the discovery of a diverse range of DNA TEs in a few insects in which genetic manipulation is actively pursued (Tu, 2001a; Holt *et al.*, 2002; Mao and Tu, unpublished data). For example, the diverse families of endogenous MITEs and DNA transposons could act as potential substrates for transposition if the introduced transposon uses similar TIRs. Thus, analyses of endogenous insect TEs will lead to better-informed design of transposon-based transformation tools that reduce instability resulting from interactions with endogenous TEs (Ashburner *et al.*, 1998; Atkinson *et al.*, 2001). It is also hoped that the non-Mendelian inheritance of TEs could help beneficial transgenes sweep through insect populations as the *P* element did in *Drosophila* (Ribeiro and Kidwell, 1994; Engels, 1997). Such a strategy is being investigated in the context of driving refractory genes into mosquito populations to control mosquito-borne infectious diseases (Ashburner *et al.*, 1998; Alphey *et al.*, 2002). A better understanding of endogenous TEs may be important to help achieve sustained success of such sophisticated genetic approaches.

4.12.9.2. SINE Insertion Polymorphism as Genetic Markers

The genetic differences and the pattern of gene flow between insect populations are of fundamental importance to a number of entomological questions ranging from evolution to practical applications. Single nucleotide polymorphisms (SNPs) are being developed as powerful markers for population genetic analysis, especially for insects with a large amount of sequence data available (Berger *et al.*, 2001). However, for most other insects, markers such as microsatellite, restriction fragment length polymorphism (RFLP) (Severson *et al.*, 1993; Yan *et al.*, 1999), cDNA-based single strand conformational polymorphism (SSCP) (Fulton *et al.*, 2001), mitochondrial (mtDNA), and ribosomal genes (rDNA) are still the tools of choice. For many insect species, finding a useful set of genetic markers is not trivial (Fagerberg *et al.*, 2001). It is clear that additional genome-wide markers are needed. Polymorphic insertion sites of interspersed TEs are potentially rich sources of genetic markers for population and genetic mapping studies. SINEs, which are especially useful for reasons described below are discussed. In population studies, sequences flanking a SINE at a specific locus are used as primers to amplify genomic DNA isolated from an individual sample. When the PCR products are run on an agarose gel, the genotype of an individual will be revealed on the basis of the number and size of bands (**Figure 11**) (see Section 4.12.7.2). Thus this locus-specific PCR assay may be used as codominant markers that reveal the dimorphism (insertion versus noninsertion) at a specific site. SINEs including the human *Alu* elements have been shown to be powerful genetic markers using the above method (Batzer *et al.*, 1994; Stoneking *et al.*, 1997; Carroll *et al.*, 2001; de Pancorbo *et al.*, 2001; Nasidze *et al.*, 2001; Roy-Engel *et al.*, 2001; Batzer and Deininger, 2002; Salem *et al.*, 2003). The ability of SINE insertion polymorphic markers to differentiate recently separated human populations is a good indication of their power (de Pancorbo *et al.*, 2001; Nasidze *et al.*, 2001; Watkins *et al.*, 2001). The locus-specific PCR assay of SINE insertions (**Figure 11**) has a few potential advantages over the popular microsatellite markers. The same SINE insertions are identical by descent. The probability that different SINEs of the same size independently insert into the same chromosomal location may be negligible (Stoneking *et al.*, 1997; York *et al.*, 1999; de Pancorbo *et al.*, 2001; Watkins *et al.*, 2001). However, the same signals in microsatellite, RFLP, SSCP, and melting curve single nucleotide polymorphism (McSNP) can only be considered identical by state, with the possibility of different origins. Moreover, the ancestral state of the SINE insertion polymorphism is likely to be the absence of a SINE because of general lack of excision, although exceptions do exist (Medstrand *et al.*, 2002). The ability to distinguish the ancestral versus derived states provides additional resolving power to address population genetic questions (York *et al.*, 1999). Because of the significant size difference of the PCR products and the dimorphic nature of the alleles, SINE insertions can be easily scored using agarose gels or melt-curve analysis, which can be developed for high-throughput analysis. Finally, a minimal amount of template is required for the PCR assay, allowing the use of a single insect for hundreds if not thousands of assays. One potential limitation of this approach could be the removal of a SINE insertion by rare recombination or gene conversion events, which may be confused with the noninsertion state. Such events may be revealed during the PCR analysis. Sequence analysis at the insertion site will also allow the investigation of this possibility. A better understanding of the evolutionary and population dynamics of SINEs will further provide theoretical foundations for this

potentially powerful method (Batzer and Deininger, 2002).

The recent development of a TE-anchored PCR approach, or TE display (see Section 4.12.5.3), has made it possible to directly screen for TE insertion polymorphism in a few species including insects (Roy *et al.*, 1999; Casa *et al.*, 2000, 2002; De Keukeleire *et al.*, 2001; Biedler *et al.*, 2003; Yang and Nuzhdin, 2003) (**Figure 9**). TE display efficiently scans a large number of loci in the genome, which makes it a very good tool for genotyping. However, as a population genetic tool, it has a major limitation common for dominant markers such as AFLP and randomly amplified polymorphic DNA (RAPD), namely the inability to distinguish between heterozygous and homozygous insertions, rendering the detection of population genetic structure difficult. However, TE display can be used as a direct screen to identify potential polymorphic insertion sites. Therefore TE display in conjunction with the development of locus-specific PCR markers that are codominant (**Figure 11**) will help TE insertion polymorphism markers reach their full potential as population genomic tools for insects. The use of TE insertion polymorphic markers in insect population studies is at an early stage. TE display and TE-based locus-specific PCR are used as genome-wide markers to investigate the genetic differences between different populations of *A. gambiae sensu stricto*, a species in the *A. gambiae* complex, and to study its ongoing speciation. These population genomic studies also have significant practical implications because genetic heterogeneity between mosquito populations can affect both the efficiency of disease transmission and the relative value of mosquito control measures (Coluzzi *et al.*, 2002; della Torre *et al.*, 2002). It was shown that different regions of the *A. gambiae* genome behave very differently with regard to introgression and gene flow (della Torre *et al.*, 2002). One important advantage of TE-based tools is the ability to scan a large number of TE insertions across different regions of the genome. Our initial TE display using *A. gambiae SINE200* showed significant differences at multiple sites between two forms of *A. gambiae sensu stricto*, namely the M and S forms (Coluzzi *et al.*, 2002). Polymorphic insertion sites for locus-specific PCR are isolated. Similar assays are also developed for *Aedes aegypti* using a SINE named *Feilai* (Tu, 1999). The development of TE-based population genomic tools for *A. aegypti* will be especially significant considering the lack of useful microsatellite markers in this species. The likely broad distribution of SINEs in insects makes them potentially rich sources of genetic markers for many different species.

4.12.9.3. SINE Insertions as Phylogenetic Markers

TE insertions, more specifically SINE insertions, have recently been used as molecular systematic tools to trace the evolutionary relationship between whales and Artiodactyla (Shimamura *et al.*, 1997; Nikaido *et al.*, 1999) and between salmonid fishes (Murata *et al.*, 1993). Perhaps the most impressive use of SINE insertions is the resolution of the evolutionary relationship of one of the major tribes of the African cichlid fishes which have evolved through an explosive adaptive radiation (Takahashi *et al.*, 1998; Terai *et al.*, 2003). To obtain TE insertion information for molecular systematics, locus-specific PCR described above is used. Here an RNA-mediated TE such as a SINE is again better suited because its transposition does not involve excison. Therefore, the ancestral state is known to be the absence of a SINE (Shedlock and Okada, 2000). The basic concept of this approach is illustrated in **Figure 12**. The insertion state can be easily determined using an agarose gel or melt-curve analysis as shown in **Figure 11**. When a fixed insertion is found at a particular site in species 1 and 2 but not in species 3, it can be inferred that species 1 and 2 are sister taxa. One of the requirements of the above approach is that the TE insertion site should be fixed within a species. TE display, a fingerprinting method described earlier (**Figure 9**), may be used to search for such sites. Potential problems such as nonspecific deletions, gene conversions, and sorting of ancestral polymorphisms can either be detected during the PCR and gel electrophoresis analysis or mitigated by surveying multiple loci (Shedlock and Okada, 2000). Sequences of the SINEs themselves in the loci used for the systematic analysis may provide further

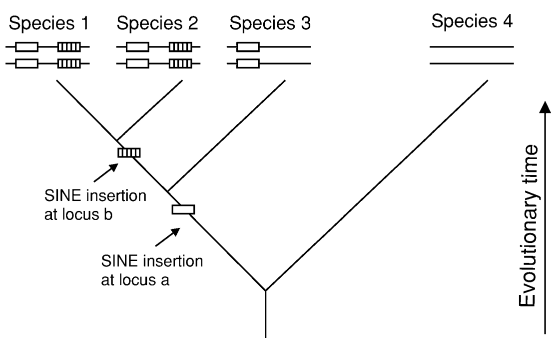

Figure 12 A schematic illustration of the principle of using SINE insertions as molecular systematic markers. Monophyletic relationship between species may be inferred on the basis of shared SINE insertions. See Section 4.12.9 for detailed explanations.

phylogenetic information. The usefulness of a particular SINE family in molecular systematics studies is dependent on its distribution and lifespan in the taxonomic group of interest. The tremendous diversity of insect species offers interesting challenges to evolutionary biologists. For example, a number of medically and economically important insect organisms exist as cryptic species complexes (Munstermann and Conn, 1997; Krzywinski and Besansky, 2003). New phylogenetic tools that can be integrated with methods using conventional characters such as morphology and DNA sequences will undoubtedly be of significance. Although SINEs have not been extensively studied in insects, highly repetitive SINEs have already been characterized in different orders including many medically and economically important species. Therefore SINEs may provide useful markers for molecular systematic analysis of insects, one of the most diverse groups of life forms on this planet.

In summary, TEs have been successfully used as vectors for genetic manipulation of insects and other organisms. A better understanding of insect TEs will allow better-informed usage of the currently available TE-based tools. The application of TEs as population and phylogenetic markers is at an early stage. Although these markers are promising tools, their scope of application, their resolving power and reliability depend on a better understanding of the population and evolutionary dynamics of the TEs. Therefore the fundamental studies dicussed in previous sections also have significant implications for the applications of TE-based molecular tools.

4.12.10. Summary

The last few years have witnessed an explosive growth both in the development of TE-based genetic and molecular tools and in our fundamental understanding of the diversity and impact of TEs in insects. Studies of TEs in insects, especially in *D. melanogaster*, have more than once led to discoveries that broadly impacted the field of TE research. The availability of new bioinformatics and experimental tools and the expanding genome revolution provide an exciting opportunity for the discovery of novel TEs in a wide range of insects and for the in-depth molecular and genomic analysis of these mobile genetic elements. Only through comparative genomic approaches, can we achieve a full appreciation of the complex and intricate dynamics governing the evolution of diverse TEs in insect genomes. From an applied perspective, systematic analysis of TEs in many insect species has significant economic and health implications because of the importance of these insects in disease transmission and agriculture.

4.13 Transposable Elements for Insect Transformation

A M Handler, US Department of Agriculture,
Agricultural Research Service, Gainesville, FL, USA
D A O'Brochta, University of Maryland
Biotechnology Institute, College Park, MD, USA

Published by Elsevier BV.

4.13.1. Introduction

The ability to create genetically transformed organisms has played a central role in the history of modern genetics, in particular, to our understanding of gene expression and development. Indeed, the pioneering transformation experiments of *Pneumococcus* by Griffith (1928) and subsequent systematic analyses by Avery *et al.* (1944), that showed transformation from a "rough" to a "smooth" bacterial cell wall phenotype, were instrumental in defining DNA as the inherited genetic material. The importance of these initial transformation experiments to prokaryotic genetic analysis was widely appreciated, and continued studies by many other laboratories laid the foundation for modern molecular biology.

The importance of "transformation" technology to eukaryotic genetic studies was apparent, and several of the initial attempts to create transgenic animals were performed in insects, though the means of achieving and assessing insect transformation were not straightforward. The primary reasons why these early attempts to create transgenic insects were largely unsuccessful were the inability to isolate and reproduce individual genetic elements that could be used as transformation vectors and markers, and the lack of efficient means of introducing DNA into germ cells. Most of the initial studies of insect transformation relied on soaking embryos or larvae, with visible mutant phenotypes, in solutions of total wild-type genomic DNA in hopes of reverting the mutant phenotype. The first experiments performed on *Bombyx* and *Ephestia* met with some success where mutant wing color pattern phenotypes were reverted in some organisms, though inheritance was inconsistent and transformation events could not be confirmed unequivocally

(Caspari and Nawa, 1965; Nawa and Yamada, 1968; Nawa *et al.*, 1971). Similar results were obtained in *Drosophila* studies (Fox and Yoon, 1966, 1970; Fox *et al.*, 1970), and for all of these initial experiments, it is most likely that the observed phenotypic changes resulted from extra-chromosomal maintainance of introduced DNA in the somatic tissue by an unknown mechanism. A different approach involving the microinjection of wild-type genomic DNA into embryos homozygous for a recessive eye color mutation (*vermilion*), resulted in transformants with a reversion to the normal red eye color phenotype. While the reversion event was genetically mapped away from the mutant locus, a thorough molecular analysis to verify a transformation event, before the lines were lost, was not achieved and so the nature of the phenomenon observed in this experiment remains unexplained (Germeraad, 1976).

In the mid-1970s a turning point in insect science occurred with the extension of molecular genetic analysis to *Drosophila melanogaster.* These early studies and subsequent studies not only provided many of the tools and reagents necessary for developing and critically assessing genetic transformation in insects, but they also emphasized the need for a technology that would facilitate a more complete understanding of the genes being isolated using recombinant DNA methods. One technology that was clearly needed was a means to integrate DNA molecules into the chromosomes of germ cells where it remained stable, resulting in heritable germline transformation. The simple introduction of raw linearized DNA into preblastoderm embryos in the hope of fortuitous recombination into host chromosomes was clearly not reliable. Interest was growing, however, in the use of mobile genetic elements as vectors for DNA integration, including retrotransposons and transposons that were being isolated in *Drosophila* for the first time. Foremost among these was the *P* transposable element, isolated from certain mutant alleles of the *white* gene. The subsequent testing and success of transformation mediated by the *P* element in the *Drosophila* germline proved to be a dramatic turning point in the genetic analysis of an insect species. The eventual impact of this technology on understanding genetic mechanisms in all eukaryotic systems cannot be understated. The success with *P* in *Drosophila* gave hope that this system could be straightforwardly extended to genetic manipulation of other insect species, and especially those highly important to agriculture and human health. While there was reason for optimism, we now realize that this was a naive expectation given what we now understand about the natural history of *P* elements relative to other Class II transposable elements, in particular its extremely limited distribution and its dependence on species-specific host factors. The inability of *P* to function in non-drosophilids, however, was a motivating force to more completely understand transposon regulation and the identification and testing of new vector systems. These included other transposable elements, as well as viral and bacterial vectors.

The development of routine methods for insect gene-transfer was probably delayed by a decade due to attention being focused exclusively on the *P* element. Yet, this delay has resulted in a more varied toolbox of vectors and markers that now allow nearly routine transformation for many important species, and the potential for transformation of most insects (see Handler, 2001). Indeed, some of the tools developed for testing the *P* element, in particular embryonic mobility assays, are now routinely used for initial tests for function of other vectors in an insect species before more laborious and time-consuming transformation experiments are attempted.

The creation of this varied toolbox was first related to the potential need for different vector and marker systems for different insect species. We now realize that the future of genetic analysis will depend on multiple vector and marker systems for each of these species, since genomics and functional genomics studies will require multiple systems for DNA integration and reporters for gene expression. Indeed, germline transformation is essential for the insertional mutagenesis and functional genomics studies that are critical underpinnings for both assessing genomic architecture and relating sequences to gene expression. Notably, the continuing functional analysis of the *Drosophila* genome now relies on the vectors and markers, described in this chapter, that were first developed for nondrosophilid insect species.

4.13.2. *P* Element Transformation

4.13.2.1. *P* Element

The use of transposable element-based vectors for *Drosophila* transformation followed the discovery of short inverted terminal repeat-type elements similar to the *Activator* (*Ac*) element discovered in maize by McClinotck (see Federoff, 1989). The first such element to be discovered in insects was the *P* element, the factor responsible for hybrid dysgenesis that occurred in crosses of males from a *P* strain (containing *P* factor) with females from an

M strain (devoid of *P* factor) females (Kidwell *et al*., 1977). The identification of *P* sequences resulted from the molecular analysis of *P*-induced *white* mutations that occurred in dysgenic hybrids (Rubin *et al*., 1982). While the initial *P* elements isolated as insertion sequences were incomplete, nonautonomous elements, complete functional elements were later isolated and characterized by O'Hare and Rubin (1983).

P is 2907 bp in length with 31 bp inverted terminal repeats (ITRs) and 11 bp subterminal inverted repeats that occur approximately 125 bp from each terminus (**Figure 1**). Other repeat sequences exist within *P*, but their functional significance, if any, remains unknown. A defining signature for *P*, as with other transposable elements, is the nature of its insertion site which consists of an 8 bp direct repeat duplication. The extensive use of *P* for transformation and transposon mutagenesis has shown the element to have a distinctly nonrandom pattern of integration. It is now clear that *P* elements are blind to a significant fraction of the genome and new gene vectors are being employed in *Drosophila* to complement these limitations. *P* elements and all transposable elements currently used as insect gene vectors belong to a general group of transposable elements known as Class II short inverted terminal repeat transposons (see Finnegan, 1989). These elements transpose via a DNA intermediate and generally utilize a cut-and-paste mechanism that creates a duplication of the insertion site. These are distinguished from Class I elements, or retrotransposons, that have long direct terminal repeats (LTRs) and transpose via reverse transcription an RNA intermediate.

The original use of *P* for germline transformation was accomplished by inserting a marker gene within the element so that it did not disrupt activity of the terminal sequences or the transposase gene. The *rosy*$^+$ gene was inserted at the 3′ end of the transposase-coding region, but upstream of the 3′ subterminal inverted repeat sequence. Plasmids containing this vector were injected into preblastoderm (syncytial) embryos homozygous for *ry*$^-$ so the *P* vector could transpose into germ cell nuclei. Germline transformation events were identified in the following generation (G_1) by virtue of reversion of the mutant *ry*$^-$ eye color phenotype to wild-type. These experiments not only proved the feasibility of transposon-mediated transformation, but also permitted structure–function relationships within the *P* element to be defined (Karess and Rubin, 1984). The *P* transcriptional unit was found to be composed of four exons separated by three introns. Further analysis determined that the *P* transposase function is cell-type specific owing to differential transcript splicing of the third intron that is limited to the germline. The lack of splicing in the soma results in production of nonfunctional truncated polypeptides in this tissue (Rio *et al*., 1986).

While the original *P* vector allowed efficient transformation, the presence of a functional transposase gene within the vector made the system self-mobilizable (autonomous) and inherently unstable, allowing potential excision or transposition of the original insertion event. Subsequent vector development resulted in a binary system in which the vector transposase was deleted or made defective by insertion of a marker gene. The ability of the transposase

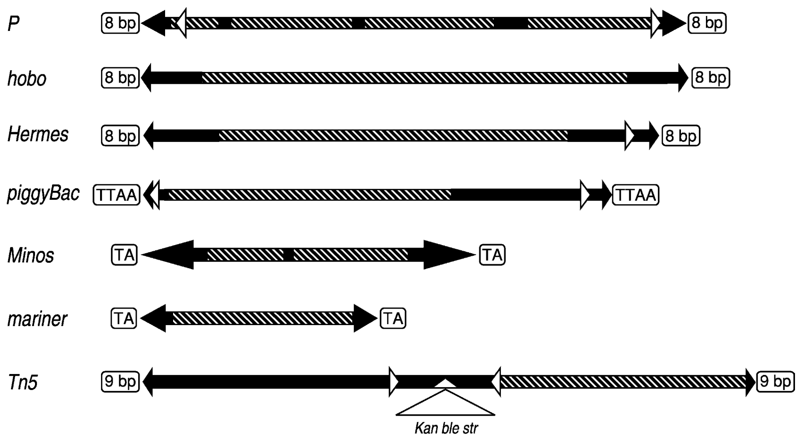

Figure 1 Diagram of transposable elements currently in use for the germline transformation of insect species. The left arms represent the 5′ termini and right arms represent the 3′ termini. Transposon sizes and specific internal elements are shown in relative positions but are not at precise scale. Major structural elements include duplicated insertion sites (open boxes); inverted terminal repeat sequences (black arrowheads); internal subterminal repeat sequences (white arrowheads); transposase coding region (boxed diagonals); and intron sequences (black boxes). The *Tn5* element is a composite transposable element consisting of two functional elements flanking three antibiotic resistance genes. Refer to text for specific details on nucleotide lengths and relative positions.

to act *in trans* allowed transposase to be provided by a separate plasmid (helper), that could facilitate vector integrations when cointroduced with the vector-containing plasmid into the same nucleus (Rubin and Spradling, 1982). Integrations would remain stable if the helper did not integrate, but the original helpers, such as pπ25.1, were autonomous *P* elements themselves that could integrate along with the vector. While helper integration was diminished by injecting much higher concentrations of vector plasmid, this possibility was only eliminated with the creation of defective helpers having one or both of their terminal sequences deleted (known as "wings-clipped" helpers). The first of these was pπ25.7wc, which was immobilized by deletion of 3′ terminal sequences (Karess and Rubin, 1984). This prototype vector system served as a model for binary systems of nonautonomous vector: helper elements used for all the transposon-based transformation systems currently in use (**Table 1**).

A notable characteristic of *P* elements was not only their discontinuous distribution within the species (*P* and *M* strains), but their discontinuous interspecific distribution. Based on its distribution patterns it has become apparent that *P* was recently introduced into *D. melanogaster* from *D. willistoni* by an unknown mechanism (Daniels and Strausbaugh, 1986). Regardless of the mechanism since the 1950s, *P* elements have thoroughly invaded wild populations of *D. melanogaster* (Anxolabéhère *et al*., 1988), and without the existence of *M* strain laboratory stocks that were removed from nature before this time, the development of *P* vectors might never have been realized. This is due to the repression of *P* mobility in *P*-containing strains that was first observed in hybrid dysgenesis studies, which also showed that movement was not repressed in *M* strains devoid of *P*. The basis for *P* strain repression appears to be due to a number of factors including repressor protein synthesis, transposase titration by resident defective elements, and regulation of transposase gene transcription (Handler *et al*., 1993b; Simmons *et al*., 2002). As will be discussed further on, other vector systems in use have thus far been shown to be widely functional in several orders of insects, and the presence of the same or related transposon in a host insect does not necessarily repress vector transposition. In this and several other aspects, the *P* vector system appears to be the exception rather than the rule for transposon-mediated gene transfer in insects.

4.13.2.2. *P* Vectors and Markers

Regardless of regulatory differences between *P* and other transposon vector systems currently in use, methods developed for *P* transformation of *Drosophila* serve as a paradigm for all other insect vector systems. Those familiar with *Drosophila* transformation will be in the best position to attempt these methods in other insects. Current techniques developed for other insect species are variations on a theme, although as we describe, considerable modifications have been made. Several comprehensive reviews are available for more specific details on the structure, function, and use of *P* for transformation in *Drosophila*, which are highly relevant to the understanding and use of other vector systems (see Karess, 1985; Spradling, 1986; Engels, 1989; Handler and O'Brochta, 1991). Particularly useful are the books and method manuals by Ashburner (1989a, 1989b) that review the various vectors, markers, and methodologies used for *Drosophila* transformation, as well as early techniques used to manipulate *Drosophila* embryos. This information is especially applicable to other insect systems.

The first consideration for transformation is the design of vector and helper plasmids, and the marker system used for transformant selection. The first *P* vectors and helpers were actually autonomous vectors, which was probably a useful starting point since the actual sequence requirements for vector mobility and transposase function were unknown. As noted, the first nonautonomous helper had a 3′ terminal deletion that prevented its transposition, providing greater control over vector stability. However, this source of transposase was inefficient, until it was placed under *hsp70* regulation which allowed transposase induction by heat shock (Steller and Pirrotta, 1986). All other vector system helper constructs have similarly taken advantage of heat shock promoters, mostly from the *D. melanogaster hsp70* gene, but other *hsp* promoters have been tested including those from the host species being transformed. Other constitutive promoters such as those from the genes for *actin* and *α1-tubulin* have proven successful for helper transposase regulation, and will be discussed further on.

While sufficient transposase production is critical for transposition, the structure of the vector is equally important, and for some, very subtle changes from the autonomous vector can dramatically decrease or eliminate mobility. These variations include critical sequences (typically in the termini and subtermini), and placement and amount of exogenous DNA inserted within the termini. For some vectors the amount of plasmid DNA external to the vector can affect transposition rates. Subsequent to the initial test of several *P* vectors, the terminal sequence requirements for *P* mobility were determined to

include 138 bp of the 5′ end and 216 bp of the 3′ end. While the inverted repeat sequences within these terminal regions are identical, the adjacent sequences were found not to be interchangeable in terms of vector mobility (Mullins *et al*., 1989). Of interest was the discovery that the strongest binding affinity for the *P* transposase was at sequences approximately 50 bp internal to the terminal repeats (Rio and Rubin, 1988; Kaufman *et al*., 1989). While the minimal sequences required for mobility may be used in vectors, typically the rate of mobility decreases with the decreased length of terminal sequence. Specific sequences may be required for binding of transposase or other nuclear factors, and conformational changes needed for recombination may be dependent upon sequence length and position.

P vector mobility was also found to be influenced by the amount of exogenous DNA inserted between the termini, with transformation frequency diminishing with increasing size. Initial tests with 8 kb vectors marked with *rosy* yielded transformation frequencies of approximately 50% per fertile G_0, while use of 15 kb vectors resulted in 20% frequencies (see Spradling, 1986). Larger vectors could transpose but frequencies approached 1% or less.

Of equal importance to creating an efficient vector system is having marker genes and appropriate host strains that will allow efficient and unambiguous identification or selection of transgenic individuals. Indeed, the genetic resources available for *Drosophila* also provided cloned wild-type DNA and appropriate mutant hosts for use in visible mutant-rescue marker systems that made testing *P* transformation possible. As noted, the first of these used the ry^+ eye color gene, but this required a relatively large genomic fragment of nearly 8 kb. The *white* (*w*) eye color gene was then tested, but this required a genomic sequence that was longer than *ry*, and resultant transformation frequencies were relatively low (Hazelrigg *et al*., 1984; Pirrotta *et al*., 1985). New *w* markers, known as mini-*white*, that had the large first intron deleted decreased the marker insert to 4 kb resulting in much more efficient transformation, and placing the mini-*white* marker under *hsp70* regulation increased efficiencies further (Klemenz *et al*., 1987). Use of *w* markers, especially in CaSpeR vectors (Pirrotta, 1988), has been a mainstay of *Drosophila* transformation, yet expression of the *w* gene in particular is subject to position effect variegation/suppression (PEV) that typically diminishes eye pigmentation. PEV, indeed, was originally discovered as a result of translocating w^+ proximal to heterochromatin (Green, 1996), and it routinely manifests itself in w^- flies transformed with w^+. This effect has been observed with the use of eye pigmentation markers in several other insect species as well.

Other markers based upon chemical selections or enzymatic activity were also developed for *Drosophila*, though none has found routine use. These included alcohol dehydrogenase (*Adh*) (Goldberg *et al*., 1983) and dopa decarboxylase (*Ddc*) (Scholnick *et al*., 1983) that complemented existing mutations, and neomycin phosphotransferase (NPT or *neo*) (Steller and Pirrotta, 1985), β-galactosidase (Lis *et al*., 1983), organophosphorus dehydrogenase (*opd*) (Benedict *et al*., 1995), and dieldrin resistance (*Rdl*) (ffrench-Constant *et al*., 1991) which are dominant selections not requiring preexisting mutations (see ffrench-Constant and Benedict, 2000).

4.13.2.3. *P* Transformation of Non-Drosophilids

Given the straightforward procedures for transforming *Drosophila* with *P* elements, there were high expectations that the system would function in other insects. The ability to test this was facilitated by the development of the neomycin (G418)-resistance marker system (Steller and Pirrotta, 1985), and neomycin resistance-containing *P* vectors were widely tested in tephritid flies and mosquitoes (see Walker, 1990; Handler and O'Brochta, 1991). Unfortunately, the neomycin resistance system was generally unreliable, and recovery of resistant individuals that were not transgenic was common. In three mosquito species, however, neomycin resistant transgenic insects were recovered but they arose from rare transposition-independent recombination events (Miller *et al*., 1987; McGrane *et al*., 1988; Morris *et al*., 1989). Other dominant chemical resistance markers, including *opd* and *Rdl*, which had had some success in *Drosophila*, were also tested, but no transformation events could be verified in other insects. A major limitation of these experiments was that, given the numerous variables involved, it was impossible to determine which components in the system were failing. This limitation led to efforts to determine systematically whether the transposon vector system was, indeed, functional in host embryos, which resulted in the development of rapid transposon mobility assays as described below. The first of these assays tested *P* excision in drosophilid and non-drosophilid embryos, revealing that *P* function decreased in drosophilids as a function of relatedness to *D. melanogaster*, with no function evident in non-drosophilids (O'Brochta and Handler, 1988; Handler *et al*., 1993a). These results were the first indication that for transposon-mediated germline transformation to succeed in non-drosophilids, new vector

systems would have to be created from existing and newly discovered transposon systems.

4.13.3. Excision and Transposition Assays for Vector Mobility

Assessing the ability of an insect gene vector to function in a particular species can be challenging. The procedures required to create a transgenic insect using transposable element-based gene vectors require a great deal of technical skill and the ability to perform basic genetic manipulations. Depending on the insect, its generation time, and its amenability to being reared in the laboratory, the process of genetic transformation can be quite lengthy. At the early stages of developing non-drosophilid transformation technology there was little experience in manipulating and injecting the embryos of the various non-drosophilid species of insects. In addition, the genetic markers available to select for, or recognize, transgenic insects were limited and none could be confidently expected to function optimally in the species being tested at that time. Consequently, early efforts to test the functionality of potential gene vectors, by attempting to create transgenic insects, required simultaneous success in dealing with a number of daunting challenges. The failure of these efforts to yield a transgenic insect could not, unfortunately, be ascribed to the failure of any one particular step in the process (see Handler and O'Brochta, 1991). These efforts, therefore, did not represent an isolated test of the gene vector since failure to obtain a transgenic insect might have been due to a failure in DNA delivery, expression of the genetic marker, or the failure of the transposable element vector system. Technology development under these conditions was very difficult. What was needed was an experimental system that permitted the activity of the transposable element system to be assessed in the species of interest independent of any prospective genetic marker system and DNA delivery system. Such a system was developed for investigating the mobility properties of the *D. melanogaster* *P* element, and was very adaptable to other transposable element and insect systems (Figure 2).

The system developed for *P* elements involved transfecting *Drosophila* cells with a mixture of two plasmids – one containing a *P* element inserted into the coding region of the LacZα peptide of a common cloning vector, and a second containing the *P* element transposase gene under the regulatory control

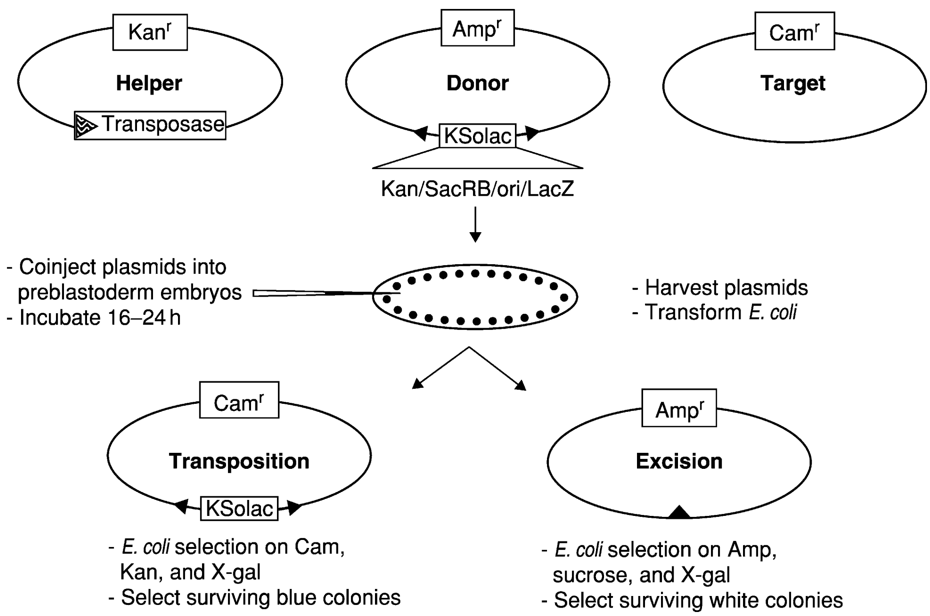

Figure 2 Plasmid-based transposable element mobility assays. A mixture of three plasmids is coinjected into preblastoderm embryos to insure incorporation into nuclei. After approximately 24 h the plasmids are extracted from the embryos and introduced into *E. coli*. Transient expression of the transposase gene on the helper plasmid in the developing embryos results in the production of functional transposase. If the transposase catalyzes excision and transposition of the element, excision will result in the loss of element-specific markers on the donor plasmid. In the example shown sucrose sensitivity, β-galactosidase activity, and kanamycin resistance are lost, and others could be used. Transposition results in the target plasmid acquiring all of the element-specific markers. In this example the target plasmid is from a Gram-positive bacteria and incapable of replicating in *E. coli* unless it acquires the origin of replication present on the element. Assays can be completed in 3 days and rates of movement of 0.001% or greater are routinely detectable.

of a strong promoter (Rio *et al*., 1986). Transient expression of the transposase gene resulted in the production of transposase, catalyzing the excision of *P* elements from the "excision indicator plasmids." Subsequent recovery of the injected plasmids from the cells, followed by their introduction into an appropriate strain of *Escherichia coli,* permitted plasmids that had lost the *P* element through excision to be recognized by virtue of their restored LacZα peptide coding capacity. This transient *P* element excision assay was readily adaptable to use in *Drosophila* embryos through the process of direct microinjection of preblastoderm embryos, and it played a critical role in assessing the functionality of the *P* element system in a variety of drosophilid and non-drosophilid insect systems (O'Brochta and Handler, 1988).

As originally configured the excision assay only permitted the identification and recovery of excision events that resulted in the restoration of the open reading frame of the LacZα peptide reporter gene. Various modifications in this basic assay were adopted that permitted precise and imprecise excisions to be identified and recovered (O'Brochta *et al*., 1991). For example, marker genes such as the *E. coli* LacZα peptide coding region, *E. coli supF*, sucrase (*SacRB*) from *Bacillus subtilis*, and streptomycin sensitivity, were incorporated into the transposable element (O'Brochta *et al*., 1991; Coates *et al*., 1997; Sundararajan *et al*., 1999). Plasmids recovered that lacked marker gene expression were usually excision events. Further refinements of the excision assay involved the use of transposable element-specific restriction endonuclease sites as a means for selecting for excision events. Digesting plasmids recovered from embryos with restriction endonucleases with sites only in the transposable element was a very powerful method of physically removing plasmids that had not undergone excision from the pool of plasmids recovered from embryos and used to transform *E. coli*. Each restriction site was essentially a single dominant genetic marker and therefore transposable elements with multiple restriction sites provided a very powerful system for selecting against plasmids that have not undergone excision (O'Brochta, unpublished data).

Continued development of element mobility assays lead to assays in which interplasmid transposition could be measured. These assays involved the coinjection of a transposase–encoding helper plasmid, an element "donor" plasmid and a "target" plasmid. Typically the target plasmid contains a gene whose inactivation results in a selectable phenotype. For example, the *SacRB* gene has been used since its inactivation eliminates sucrose sensitivity. If the donor element also contains unique genetic markers then transposition events would lead to a recombinant plasmid with a new combination of a variety of markers (Saville *et al*., 1999). Perhaps the most powerful transposition assay developed for assessing transposable elements in insect embryos involved the use of a genetic marker cassette containing a plasmid origin of replication, an antibiotic resistance marker, and the LacZα peptide coding region, in combination with a target consisting of a Gram-positive plasmid (pGDV1) (Sarkar *et al*., 1997a). pGDV1 contains an origin of replication that cannot function in *E. coli,* although it does have a chloramphenicol resistance gene that is functional in this species. Transposition of the marked transposable element into pGDV1 converts it into a functional replicon in *E. coli*. Because of the absolute *cis*-dependence of origins of replication, and the complete inability of pGDV1 to replicate in *E. coli,* transposition events can be readily detected even at low frequencies.

Transient mobility assays are now a standard for defining vector competence in insect embryos, and in particular, when assessing a vector in a species for the first time. For this application, transposition assays provide the most information relevant to the potential for successful germline transformation, and can be used as a system to test helper construct function. As noted below, however, there may be differing constraints on plasmid and chromosomal transpositions for particular transposons. The use of these assays for analyzing transposon function is discussed in more detail in the relevant sections below.

Embryonic assays also provide an essential test system for assessing potential transgene instability by mobilizing or cross-mobilizing systems within a host genome, which is a critical information for the risk analysis of transgenic insects being considered for release. The importance of excision assays for this purpose became evident by the *hobo* excision assays in *Musca domestica* that revealed the existence of the *Hermes* element (Atkinson *et al*., 1993), and the subsequent assays that defined the interaction between the two transposons (Sundararajan *et al*., 1999). Since cross-mobilizing systems do not always promote precise exicisions, assays that reveal imprecise as well as precise excisions are most sensitive for this purpose. Since successful transposition may depend on precise excision, transposition assays may only reveal the existence of mobilizing systems that have a high level of functional relatedness.

4.13.4. Transformation Marker Systems

The availability and development of selectable marker systems has played a large part in recent

advancements in insect transformation, that have been equal to the importance of vector development. The rapid implementation and expansion of *P* transformation in *Drosophila* was possible, in large part, due to the availability of several eye color mutant-rescue systems. These systems depend on the transgenic expression of the dominant-acting wild-type gene for an eye color mutation present in the host strain (see Sarkar and Collins, 2000). Successful transformation of non-drosophilid species was similarly dependent upon the development of analogous systems, with the first transformations in the medfly, *Ceratitis capitata*, and a mosquito, *Aedes aegypti*, relying on *white* and *cinnabar* mutant-rescue systems. While chemical resistance markers were used initially for non-drosophilid transformation, and can be highly useful for specific applications, their inefficiency and inconsistency when used alone provided ambiguous results for several species (see ffrench-Constant and Benedict, 2000). Eye color marker systems are generally efficient and reliable, and cloned wild-type genes from *Drosophila* often complement orthologous mutant alleles in other insects. However, only a handful of species have stable mutant strains that can serve as suitable hosts for mutant-rescue strategies. The most significant advancement in marker gene development for the wide use of insect transformation has been the development of fluorescent protein markers (Higgs and Sinkins, 2000; Horn *et al*., 2002). As dominant-acting neomorphs, that do not depend on preexisting mutations, they are directly useful in almost all host strains. When compared to the *white* eye color marker in *Drosophila*, the enhanced green fluorescent protein (EGFP) gene seemed to be less affected by position effect suppression, and thus has the additional advantage of more reliable detection (Handler and Harrell, 1999). Certainly for the forseeable future, fluorescent protein markers will continue to be the markers of choice for most insect transformation strategies.

4.13.4.1. Eye Color Markers

The first insect transformations used mutant-rescue systems to identify transformant individuals, but in these experiments total genomic DNA was used, rather unreliably, to complement mutations in the respective host strains. The most reliable of these, however, was reversion of the *vermilion* eye color mutation in *D. melanogaster* (Germeraad, 1976). The success of the initial *P* element transformations in *Drosophila* also depended on reversion of eye color mutant strains, but the use of cloned *rosy* and *white* genomic DNA within the vector plasmid allowed for much greater efficiency and reliability. The first non-drosophilid transformations in medfly (Loukeris *et al*., 1995b; Handler *et al*., 1998; Michel *et al*., 2001) similarly relied on use of the wild-type medfly *white* gene cDNA that was placed under *Drosophila hsp70* regulation (Zwiebel *et al*., 1995). This gene complemented a mutant allele in a *white eye* medfly host strain that was isolated more than 20 years earlier. The medfly *white* gene also complemented the orthologous gene mutation in the oriental fruit fly, yielding in one line a nearly complete reversion (Handler and McCombs, 2000). The first transformations in *A. aegypti* used a kynurenine hydroxylase-*white* mutant host strain, but for these tests the complementing marker was the *D. melanogaster cinnabar* gene (Cornel *et al*., 1997). The *D. melanogaster vermilion* gene, that encodes tryptophan oxygensase (*to*) has also been used to complement the orthologous *green* eye color mutation in *M. domestica* (White *et al*., 1996), and the *Anopheles gambiae* tryptophan oxygensase gene complements *vermilion* in *Drosophila* (Besansky *et al*., 1997). The *vermilion* and *cinnabar* orthologs have also been cloned from *Tribolium*, and while the *white* mutation in this species is complemented by tryptophan oxygensase, no preexisting eye color mutation is complemented by kynurenine hydroxylase (Lorenzen *et al*., 2002). The use of eye color mutant-rescue systems has certainly been critical to initial advances in insect transformation, and these markers should have continued utility for those species that have been successfully tested. The use of these markers, however, for the development of insect transformation in other species will be limited by the availability of suitable mutant host strains.

4.13.4.2. Chemical Selections

Previous to the development of mutant-rescue marker systems, transformant selections in non-drosophilid insects focused on genes that could confer resistance to particular chemicals or drugs. Importantly, these types of selections could be used for screening transformants en masse by providing the selectable chemical or drug in culture media. Ideally, only transformant individuals would survive the selection, allowing the rapid screening of large numbers of G_1 insects. For vectors that are inefficient and insects that are difficult to rear, the efficient screening of populations can be essential to identifying transformant individuals. The first drug resistance selection tested used the bacterial neomycin phosphotransferase gene (NPT II or *neomycin*^{r}) that conferred resistance by inactivation of the neomycin analog G418 (or Geneticin) (Steller

and Pirrotta, 1985). This seemed straightforward since the selection and *hsneo* marker system (putting NPT II under heat shock regulation) was already developed and tested in *Drosophila* for mass transformant screens, and the bacterial resistance gene was thought to be functional in most eukaryotes. The initial *P* transformations in *Drosophila* using the pUChsneo vector were generally reliable; however, the marker was not easily transferable to other species. G418 resistance was highly variable, most likely due to species differences in diet, physiology, and symbiotic bacteria, and indeed, variations in resistance in transformed *Drosophila* have been attributed to strains of yeast used in culture media (Ashburner, 1989a). Other chemical resistance markers, including *opd* conferring resistance to paraoxan (Phillips *et al*., 1990; Benedict *et al*., 1995), and the gene for dieldrin resistance (*Rdl*) (ffrench-Constant *et al*., 1991), that were initially tested in *Drosophila* were also problematic when tested in other species. These failures were due in large part to ineffective vector systems, but a common attribute in these studies was the selection of individuals having nonvector related or natural resistance to the respective chemical. While naturally resistant insects could be selected out by molecular tests in primary transformant screeens, the recurrence of resistant insects in subsequent generations would make use of the transgenic strains highly impractical.

While the problems cited made chemical resistance selections frustrating for several species, and they have not been used for any recent transformation experiments, some successes were reported and the need for mass screening still exists. The initial tests for *P* transformation in several mosquito species used the pUChsneo vector with G418 resistant transformants being selected, though transformation frequencies were low and all of them resulted from fortuitous recombination events and not *P*-mediated transposition (Miller *et al*., 1987; McGrane *et al*., 1988; Morris *et al*., 1989). Nonetheless, chemical selections can be very powerful, and if reliable, they would dramatically improve the efficiency of transformation screens for most insects. It is quite possible that many species will not be amenable to current transformation techniques without markers that allow selection en masse. A potential means of increasing the reliability of chemical resistance screens would be to link a resistance marker to a visible marker within the vector. Initial G_1 transformants could be screened en masse by chemical resistance, with surviving individuals verified as transformants and maintained in culture by use of the visible marker. This type of marking is tested by linking the *hsneo* construct with a red fluorescent protein marker in the *piggyBac* vector. Thus far initial results in *Drosophila* are highly encouraging (Handler and Harrell, unpublished data).

Of the enzyme systems tested for chemical selection in *Drosophila* that might be extended to other insects, the *Adh* system might have the most promise (Goldberg *et al*., 1983). An *Adh* marker gene can complement the *adh* mutation in *Drosophila*, eliminating lethal sensitivity to ethanol treatment in mutant hosts. An *adh* gene has been cloned from the medfly, and a strategy has been developed to use it for genetic sexing by male-specific overexpression (Christophides *et al*., 2001). Conceivably a similar strategy could be extended to transformant selections, though its use would be limited to medfly and possibly other tephritid species.

4.13.4.3. Fluorescent Protein Markers

The dramatic advancement of insect transformation in recent years has been due, primarily, to the development of fluorescent protein markers which are dominant-acting neomorphs that do not depend on preexisting mutations. The first of these to be tested was the green fluorescent protein (GFP) gene that was isolated from the jellyfish *Aequorea victoria* (Prasher *et al*., 1992) and which initially exhibited heterologous function in the nematode *Caenorhabditis elegans* (Chalfie *et al*., 1994). GFP expression was then tested in transformant *Drosophila* where it was used as a reporter for gene expression (Plautz *et al*., 1996; Hazelrigg *et al*., 1998), and several other species for both *in vivo* and *in vitro* studies. GFP was first tested in non-drosophilid insects as marker for Sindbis viral infection in *Aedes aegypti* (Higgs *et al*., 1996), and the dramatic somatic expression of GFP in adults was highly encouraging for the further use of GFP for germline transformants.

This possibility was first tested in *Drosophila* using a construct that linked EGFP to a *polyubiquitin* promoter and nuclear localizing sequence (Lee *et al*., 1988; Davis *et al*., 1995; Handler and Harrell, 1999). A control for transformation, that also allowed a direct comparison of EGFP expression to that from the visible mini-*white* marker, was the initial use of a *piggyBac* vector, pB[Dm*w*, PUbnlsEGFP], that linked the two markers in a mutant *white* strain. The results from this experiment indicated that not only was the PUbnslEGFP marker efficient and easily detectable under epifluorescense optics, but that many of the G_1 transformants that expressed GFP did not express a detectable level

of *white*$^{+}$. Presumably the chromosomal position effects that suppressed *white* had a negligible effect on GFP expression. This result was highly encouraging for the use of GFP as a marker in nondrosophilids and several subsequent transformation experiments used EGFP regulated by a variety of promoters in *piggyBac, Hermes*, and *Minos* vectors. Notably, this allowed germline transformation to be tested in several species that otherwise have no visible marker systems, such as the Caribbean fruit fly, *Anastrepha suspensa*, which was transformed with pB[PUbnlsEGFP] (Handler and Harrell, 2000). This vector was subsequently tested in the Australian sheep blowfly, *Lucilia cuprina* (Heinrich *et al*., 2002) and the mosquito *Anopheles albimanus* (Perera *et al*., 2002). Similarly, a *Hermes* vector marked with EGFP regulated by the *Drosophila actin5C* promoter was first tested in *Drosophila* (Pinkerton *et al*., 2000), and was used then to efficiently select transformants in *Aedes aegypti* (Pinkerton *et al*., 2000), *Stomoxys calcitrans* (O'Brochta *et al*., 2000), and *Culex quinquefasciatus* (Allen *et al*., 2001). A *Minos* vector marked with *actin5C*-EGFP was used to select *Anopheles stephensi* transformants (Catteruccia *et al*., 2000b), and a *piggyBac* vector marked with EGFP under *Bombyx actin 3A* promoter regulation was used to transform the lepidopteran species *Bombyx mori* (Tamura *et al*., 2000) and *Pectinophora gossypiella* (Peloquin *et al*., 2000).

Both the *polyubiquitin* and *actin* promoters have activity in all tissues throughout development, making insects marked in this fashion particularly useful for some applications such as the marking of insects used in biocontrol release programs (see Handler, 2002b). However, the detection of these markers can be limited due to quenching or obstruction by melanized cuticle or scales, and fluorescent protein expression regulated by a strong tissue-specific promoter can be valuable for difficult insects and particular applications. Foremost among these markers have been a series of fluorescent protein constructs regulated by the artificial 3xP3 promoter derived from the *Drosophila eyeless* gene (Sheng *et al*., 1997; Horn *et al*., 2000). The markers express strongly from the larval nervous system and adult eyes and ocelli. A 3xP3–EGFP marker within *piggyBac* was first used to transform *D. melanogaster* and *Tribolium castaneum* (Berghammer *et al*., 1999) and has since been used in *M. domestica* (Hediger *et al*., 2000), *Aedes aegypti* (Kokoza *et al*., 2001), and the sawfly *Athalia rosae* (Sumitani *et al*., 2003). The particular strengths and weaknesses for a marker construct such as 3xP3–EGFP is evident from experiments where it allowed transformant selection in *Bombyx* embryos prior to larval hatching (Thomas *et al*., 2002), while it was undetectable in *Aedes aegypti* adults having normal eye pigmentation (Kokoza *et al*., 2001). It must, therefore, be recognized that the utility of fluorescent protein markers must be considered in the context of the host insect's structure and physiology during development.

GFP expression is less sensitive to position effect suppression than eye color markers, yet there is much evidence for quantitative and qualitative variabilities in fluorescent protein expression from transgenes. It is likely that tissue-specific variations are primarily due to position effects, while expression of new tissue phenotypes are due to proximal enhancer effects. Polyubiquitin-regulated EGFP expression is most intense in the thoracic flight mucles in *Drosophila* and tephritid fruit fly adults. In Caribbean fruit fly transgenic adult lines, EGFP was only observed in the thorax, but spectrofluorometric assays revealed as much as fivefold differences in fluorescence between lines having the same number of vector integrations (Handler and Harrell, 1999), and differences in expression that are stable within lines are often observed by inspection. In contrast to typical thoracic expression in tephritid flies, adult PUb-EGFP expression in *Lucilia* was limited to female ovaries (Heinrich *et al*., 2002), and a PUb-DsRed transgenic medfly line exhibits most intense expression in the tarsi while another line expresses in abdominal tracheal apertures at the dorsal–ventral midline (Handler and Krasteva, unpublished data). In *Tribolium*, 3xP3–EGFP expresses typically from the eyes and brain, though several lines are atypical with one having muscle-specific expression throughout development (Lorenzen *et al*., 2003). In *Anopheles stephensi*, the 3xP3–EGFP marker showed atypical expression in the pylorus, epidermal cells and in a subset of cells in the rectum (O'Brochta, Kim, and Koo, unpublished data).

The use of GFP will certainly be continued for transformant identification in many, if not most, other species where transformation is tested. Yet continuing studies in species already transformed will require multiple marking systems that are distinguishable from one another, especially when coexpressed. This will allow the detection of multiple independent transgenes when used in concert for conditional gene expression systems and gene discovery methods such as enhancer traps (Bellen *et al*., 1989; Wilson *et al*., 1989; Brand *et al*., 1994). After testing 3xP3–EGFP, the 3xP3 promoter was linked to the GFP redshifted variants that emit blue (BFP), cyan (CFP), and yellow (YFP) fluorescence; these were

tested in *Drosophila*, and have proven useful individually as reporters and for identifying transformants (Horn and Wimmer, 2000). BFP and GFP have distinct enough emission spectra to be used together, though BFP photobleaches quickly and is not useful for many applications. While use of EGFP with ECFP is also problematic, ECFP and EYFP can be distinguished when using appropriate filter sets. For details on appropriate filter sets for particular applications see Horn *et al*. (2002) and the website for Chroma Technology Corp. (Chroma, 2004) which manufactures filters for most of the stereozoom fluorescence microscopes used for insect studies.

The most spectrally distinct fluorescent protein distinct from GFP and its variants is a red fluorescent protein, known as DsRed, isolated from the Indo-Pacific sea coral *Discosoma striata* (Matz *et al*., 1999). It was first tested in insects by linking it to the *polyubiquitin* promoter in a *piggyBac* vector (pB[PUb-DsRed1]) and tested in *Drosophila*, where it exhibited highly intense expression (Handler and Harrell, 2001). Importantly, DsRed expression was completely distinguishable from EGFP when the two transgenic lines were interbred, and when coexpressed as an hsp70-Gal4/UAS-DsRed reporter in lines having vectors marked with EGFP. DsRed has since been incorporated into several mosquito and fruit fly species (Nolan *et al*., 2002; Handler, unpublished data).

Both EGFP and DsRed are highly stable and generally resistant to photobleaching, and could be detected in tephritid flies several weeks after death, though DsRed1 was relatively the more stable of the two. This is highly advantageous for the use of these genes as markers for released insects that might only be retrieved several weeks after death in traps. A drawback for fluorescent proteins, and DsRed in particular, is that they require oligomerization and slow maturation that can take up to 48 h, resulting in low intensity in early development. However, variants of DsRed with shorter maturation times (Campbell *et al*., 2002), and new fluorescent proteins with enhanced properties for specific applications are becoming available on a consistent basis (see Matz *et al*., 2002).

4.13.4.3.1. Detection methods for fluorescent proteins Once heterologous expression of GFP in nematodes was discovered it was realized that use of the marker for whole-body analysis of gene expression would require an optical system allowing a large depth of field and a stage with working space for culture plates. Up to this time, most epifluoresence systems were linked to compound or inverted microscopes that had limited field depth and capability to manipulate organisms under observation. This led to the development of an epifluorescence module using a mercury lamp that could be attached to a Leica stereozoom microscope system. Most major microscope manufacturers now market integrated epifluorescent stereozoom microscopes with capabilities for several filter systems.

A lower cost alternative for GFP screening is use of a lamp module using ultra bright blue light emitting diodes (LEDs) with barrier filters that attaches to the objective lens of most stereozoom microscopes (BLS Ltd., Budapest, Hungary). It costs considerably less than a mercury lamp system, but at present, it only has capabilities for detecting GFP and YFP.

The use of fluorescent protein markers, and especially multiple markers will be greatly aided by the use of fluorescence activated embryo sorters. A device first developed to sort *Drosophila* embryos expressing GFP (Furlong *et al*., 2001) has been modified and commercially marketed for *Drosophila* and other organisms by Union Biometrica (Somerville, MA, USA). The latest sorting machines are highly sensitive having the ability not only to distinguish different fluorescent proteins, but also to discriminate between levels of fluoresence from the same protein. Thus, these systems may have enormous importance to the straightforward screening for transgenics, and more sophisticated assays such as those for enhancer traps. Practical applications could include the screening of released transgenic insects caught in traps (in systems adapted for adults), or for genetic-sexing of embryos having a Y-linked or male-specific fluorescent marker.

4.13.5. Transposon Vectors

4.13.5.1. *Hermes*

4.13.5.1.1. Discovery, description, and characteristics *Hermes* is a member of the *hAT* family of transposable elements and is related to the *hobo* element of *D. melanogaster*, the *Ac* element from maize, *Zea mays*, and the *Tam3* element from *Antirrhinum majus* (Warren *et al*., 1994). The initial interest in this family of elements by those interested in creating new insect gene vectors stemmed from two observations. First, during the middle and late 1980s the mobility characteristics of the *Ac/Ds* element system were being extensively studied because the element was recognized as having great potential to serve as a gene-analysis and gene-finding tool in maize and other plants. In addition, the mobility properties of *Ac/Ds* were being extensively tested in species of plants other than maize and in almost

every case evidence for *Ac/Ds* mobility was obtained (Fedoroff, 1989). *Ac/Ds* appeared to be a transposable element with a very broad host range, unlike, for example, the *P* element from *D. melanogaster*, which only functions in closely related species (O'Brochta and Handler, 1988). Because transposable elements with broad host ranges were of interest to those attempting to develop insect transformation technology, *Ac*-like elements warranted attention. The second significant observation at this time was that the *hobo* element from *D. melanogaster* had notable DNA sequence similarity to *Ac/Ds*, suggesting that it was a distant relative of this broadly active element (Calvi *et al*., 1991). Investigation into the host range of *hobo* using plasmid-based mobility assays (as described above) ensued (O'Brochta *et al*., 1994). It was during the investigation of *hobo* that *Hermes* was discovered (Atkinson *et al*., 1993). Atkinson *et al*. (1993) performed plasmid-based *hobo* excision assays in embryos of *M. domestica* as part of an initial attempt to assess the host range of *hobo*. Assays were performed in the presence of *hobo*-encoded transposase and *hobo* excision events were recovered suggesting that *hobo*, like *Ac/Ds*, would have a broad host range. However, when the assays were performed without providing *hobo*-encoded transposase *hobo*, excision events were still recovered in *M. domestica*. The movement of *hobo* in the absence of *hobo*-transposase was completely dependent upon the inverted terminal repeats of *hobo* and the resulting excision events had all of the characteristics of a transposase-mediated process. It was proposed that *M. domestica* embryos contained a *hobo* transposase activity and that this activity arose from the transposase gene of an endogenous *hobo*-like transposable element (Atkinson *et al*., 1993). These investigators were eventually able to confirm their hypothesis and the element they discovered was called *Hermes* (Warren *et al*., 1994).

Hermes is 2749 bp in length and is organized like other Class II transposable elements in that it contains ITRs and a transposase-coding region (**Figure 1**). It contains 17 bp ITRs with 10 of the distal 12 nucleotides being identical to the 12 bp ITRs of *hobo*. *Hermes* encodes for a transposase with a predicted size of 72 kDa and based on the amino acid sequence is 55% identical and 71% similar to *hobo* transposase (Warren *et al*., 1994). The cross-mobilization of *hobo* by *Hermes* transposase that was proposed by Atkinson *et al*. (1993) was tested directly by Sundararajan *et al*. (1999). These investigators used plasmid-based excision assays in *D. melanogaster* embryos to show that *hobo* transposase could mobilize *Hermes* elements and that *Hermes* transposase could mobilize *hobo* elements (Sundararajan *et al*., 1999). The phenomenon of cross-mobilization has important implications for the future use of transposable element-based gene vectors in non-drosophilid insects and will be discussed below. As is typical of transposable elements, *Hermes* is present as a middle repetitive sequence within the genomes of multiple strains of *M. domestica* and in all populations examined there appeared to be full-length copies of the element. The natural history of this element within *M. domestica* has not been investigated and its mobility properties within this species and the existence of any regulatory system remain unknown.

4.13.5.1.2. Patterns of integration The integration behavior of *Hermes* has been examined in a variety of contexts. Sarkar *et al*. (1997a, 1997b) tested the ability of *Hermes* to transpose, using a plasmid-based assay, in five species of Diptera. They recovered transpositions of *Hermes* in the target plasmid at a frequency of approximately 10^{-3} in all species tested. In addition they examined the distribution of 127 independent transposition events into the 2.8 kb plasmid used as a target in their assay and observed a distinctly nonrandom pattern of integrations. Most notable was the existence of three sites that were targets for *Hermes* integration 10 or more times each. In an experiment in which any site used two or more times was considered a hot spot for integration, the three sites used 10 or more times constitute sites with unusual characteristics. The precise nature of those characteristics however could not be defined. The sites shared four of eight nucleotides of the target site in common (GTNNNNAC); however, other sites with this nucleotide composition were not equally attractive as integration sites indicating that other factors must be influencing target choice. Saville *et al*. (1999) demonstrated that sequences flanking *hobo* integration hot spots were critical for determining the targeting characteristics of a site. These investigators were able to move an 8 bp *hobo* target site from plasmid to plasmid without losing its target characteristics as long as they included 20 bp of flanking sequence on each side of the target. It was suggested that proximity to a preferred integration site increased the likelihood of a site being used as a target (Sarkar *et al*., 1997a). They found that sites 80 and 160 bp flanking the integration hot spot were also preferred integration sites. The authors suggested that nucleosomal organization of the target contributes significantly to the target site selection process and contributed to the local juxtaposition of hot spots and flanking DNA.

4.13.5.1.3. Structure–function relationships Many Class II transposable elements contain a distinct amino acid motif within their catalytic domains consisting of two aspartate residues and a glutamate. This DD35E motif can be found in many but not all Class II transposable elements. The presence of this motif in *Hermes* transposase has been unclear. Bigot *et al.* (1996) proposed the existence of a DDE motif among members of the *hAT* family. However, they proposed that the second aspartate was replaced by a serine in *Ac*, *hobo*, and *Hermes*. Capy *et al.* (1996) concluded that *hAT* elements, like *P* elements from *Drosophila*, do not contain the DDE motif based on sequence alignments, and Lerat *et al.* (1999) supported this conclusion based on the lack of similarity in predicted secondary structure of the transposase of members of the *mariner/Tc* superfamily and *hobo* transposase. Michel *et al.* (2002) examined experimentally the importance of D402, S535, and E572 to the proper functioning of *Hermes* transposase. They found that mutations D402N and E572Q abolished transposase activity while the mutations S535A and S535D had no effect on transposase activity. The work of Michel *et al.* (2002) provided the first experimental data to support the hypothesis that the positive charge of residues D402 and E572 are required for transposition. The authors concluded, based on these data, that D402, S535, and E572 do not constitute the catalytic center of *Hermes* transposase because one of the residues was not essential for activity. Therefore, *Hermes* (and *hAT* elements in general) do not appear to be of the DD35E type of transposable elements, making them distinct from *mariner/Tc* elements.

Because *Hermes* transposase acts within the nucleus it is expected to contain a nuclear localization signal to direct the mature transposase from the ribosome to the nucleus. Deletion and site-directed mutagenesis analysis were performed that demonstrated that the *Hermes* nuclear localization signal is located at the amino acid end of the protein and divided among three domains (Michel and Atkinson, 2003).

The ITRs of transposable elements play an essential role in their mobility. Altering the sequence of ITRs can, depending on the element, lead to loss of function, hyperactivity of the element, or switching the mode of transposition from a cut-and-paste mechanism to a replicative mechanism. *Hermes* contains imperfect ITRs with a 2 bp mismatch within the ITR (Warren *et al.*, 1994). In addition, a naturally occurring polymorphism in the terminal nucleotide of the right 3′ ITR exists. Elements with a cytidine in the terminal position of the right ITR have no activity within *D. melanogaster* but are capable of undergoing an aberrant form of transposition in mosquitoes. Small pentanucleotide motifs in the subterminal regions of both *Hermes* and *hobo* have been found to be important for the mobilization of *Hermes* and *hobo*. The sequences GTGGC and GTGAC are interspersed throughout the subterminal region of the element, and similar repeats are present in the subterminal regions of *Ac* and are known to be transposase binding sites. In *Hermes*, altering a single repeat can eliminate transpositional activity (Atkinson *et al.*, 2001).

Hermes transposase is capable of dimerizing and one region of the protein critical for dimerization is located in the C-terminus of the protein including amino acids 551–569. This region is not only essential for dimerization but is also required for transposition activity. A second region that affects dimerization is located in the N-terminus of the protein within the first 252 amino acids of the transposase. However, this region apparently plays a nonspecific role in dimerization (Michel *et al.*, 2003).

4.13.5.1.4. Host range of *Hermes* *Hermes* has a wide insect host range and has been found to function (as measured by either plasmid-based mobility assays or by germline transformation) in at least 13 species of insects including 11 flies, one beetle, and one moth (Atkinson *et al.*, 2001). *Hermes* functions rather efficiently in *D. melanogaster* and transforms this species at rates of 20–40% (O'Brochta *et al.*, 1996). In all other species tested the efficiency of transformation was considerably lower and tended to be less than 10%. For example, *T. castenaeum* was transformed at a rate of 1%, *A. aegypti* at 5%, *C. quinquefasciatus* at 11%, *C. capitata* at 3%, and *S. calcitrans* at 4% (Atkinson *et al.*, 2001). In all insects except mosquitoes, *Hermes* appeared to use a standard cut-and-paste type mechanism as is typical of most Class II transposable elements. Such integrations are characterized by the movement of only those sequences delimited by the ITRs, and the integrated elements are flanked by direct duplications of 8 bp. Integration of *Hermes* into the germline of *A. aegypti* and *C. quinquefasciatus* appears to occur by a noncanonical mechanism resulting in the integration of DNA sequences originally flanking the element on the donor plasmid. The amount of flanking DNA that accompanies the integration of *Hermes* in these mosquito species varies. In some cases two tandem copies of the *Hermes* element were transferred to the chromosome and each copy was separated by plasmid DNA sequences (Jasinskiene *et al.*, 2000). Although

these transposition reactions are unusual they are dependent upon *Hermes* transposase since the introduction of *Hermes*-containing plasmid DNA in the absence of *Hermes* transposase failed to yield transformation events. The germline integration behavior of *Hermes* in mosquitoes is not unique; however, other elements being used as gene vectors such as *mariner* and *piggyBac* have occasionally shown similar behavior in *A. aegypti* (O'Brochta, unpublished data). Transposition assays performed with plasmids in developing mosquito embryos and in mosquito cell lines showed that *Hermes* could transpose via a canonical cut-and-paste type mechanism under these conditions (Sarkar *et al*., 1997b). The basis for the difference in types of integration events between plasmid-based transposition assays and chromosomal integrations is unknown but may reflect differences in somatic and germ cells. In *Aedes*, canonical cut-and-paste transposition has been readily detected in the somatic tissues of insects containing an autonomous element. Germline transposition in these same insects has not been detected. It has been suggested that mosquitoes might contain endogenous *hAT* elements that affect the ability of *Hermes* elements to be integrated precisely. An alternative suggestion is that *Hermes* may have a second mode of transposition as do the transposable elements *Tn7*, *IS903*, and *Mu*, which utilize a replicative mechanism of integration. Such a mechanism would result in integration products that resemble those observed in the germline of *A. aegypti* and *C. quinquefasciatus*. Replicative transposition of *Hermes* has not been demonstrated experimentally and direct tests of the "alternate mechanism" hypothesis have not been reported.

4.13.5.1.5. Postintegration behavior Once integrated into the genome of *D. melanogaster*, *Hermes* maintains its ability to be remobilized and has shown mobility characteristics that are similar to other transposable elements. Following the introduction of an autonomous *Hermes* element in which the transposase gene was under *hsp70* promoter regulation, and also contained an EGFP marker gene under constitutive regulatory control of the a*ctin5C* promoter, Guimond *et al*. (2003) found that the element continued to transpose in the germline at a rate of 0.03 jumps per element per generation. The element used in this study was also active in the somatic tissue and they used this as a means of collecting approximately 250 independent transposition events. Analysis of somatic integration events revealed a number of interesting patterns. First, they found that transpositions were clustered around the original integration event. On average 39% of the *Hermes* transpositions recovered were intrachromosomal and 17% were within the same numbered polytene chromosome division. Ten percent of the new insertions were at sites within 2 kb of the donor element, indicating that *Hermes*, like other transposable elements, shows the characteristic of local hopping. Local hopping refers to the tendency of some elements to preferentially integrate into closely linked sites. Local hopping has been described for a number of elements and is likely to be a general characteristic of Class II transposable elements although the mechanistic basis for this behavior is unknown. Certain regions of the *D. melanogaster* genome, as defined by numbered divisions of the polytene chromosomes, are preferred as integration sites, with these regions being repeatedly targeted by *Hermes*. The observed clustering of independent transposition events in regions of the chromosome seems to reflect undefined aspects of the transposition process that might be influenced by the chromatin landscape. With one exception, the clustering observed by Guimond *et al*. (2003) was not correlated with any common feature of the chromosomes or the genes within a region. This type of nonrandom pattern of integration with regional differences has also been reported for other elements. Interestingly, there does not seem to be any strong correlation between the preferred insertion-site regions of the elements *P*, *hobo*, and *Hermes*, at least with respect to chromosome 3 of *D. melanogaster* (see figure 7 from Guimond *et al*., 2003). Guimond *et al*. (2003) also observed a notable clustering of integrations in polytene chromosome division 5. Eight of the 11 integration events recovered from division 5 (3.2% of all the transposition events examined) were within the 2.7 kb segment of DNA upstream of the cytoplasmic actin gene, *actin5C*. This same 2.7 kb segment of the 5′ regulatory region of a*ctin5C* was also present within the autonomous *Hermes* element, as a promoter for the EGFP marker, which the investigators tracked as it jumped within the genome.

The strong clustering of transpositions in a target sequence that is homologous to a sequence contained within the vector has been referred to as "homing." This type of target site selection bias was first described for *P* elements and has been reported on a number of occasions. It was initially reported as a strong bias in the integration site distribution of a number of primary germline integration events in which a *P* element containing the *engrailed* gene preferentially integrated into the *engrailed* region of the host genome (Hama *et al*., 1990; Kassis *et al*., 1992). A similar biasing of integration site selection was also observed with *P* elements containing *Bithorax*

and *Antennapedia* regulatory sequences (Engstrom *et al*., 1992; Bender and Hudson, 2000). Taillebourg and Dura (1999) reported a remarkable example of homing of a remobilized *P* element in *D. melanogaster.* This element contained either an 11 kb or 1.6 kb fragment of the 5′ region of the *linotte* gene, and it was found that 20% of the remobilized elements integrated into the 5′ region of the *linotte* gene. Insertions in this case were highly localized and most occurred within a 36 bp fragment of the *linotte* regulatory region. *Hermes* homing indicates that the phenomenon is not element specific, but may be a general characteristic of Class II elements. Guimond *et al*. (2003) suggested that homing was a special case of local hopping, and the physical proximity between donor elements and target sites seems to underlie the phenomenon of local hopping. The presence of transgene regulatory sequences (e.g., *actin5C* 5′ region) may promote tethering of the donor elements to similar regulatory regions via proteins with common DNA binding sites. Deliberate tethering or transposable elements to selected sequences may be a means to regulate target site selection and to minimize the detrimental mutagenic effects of transposable element integration (Bushman, 1994; Kaminski *et al*., 2002).

The postintegration behavior of the same autonomous *Hermes* element described above in *A. aegypti* had quite different characteristics. In this case germline transposition of the autonomous *Hermes* element was never detected, and it should be noted that the primary integration events in the germline involved the integration of DNA sequences flanking the element (Jasinskiene *et al*., 1998, 2000). Despite the fact that the element was intact and that functional transposase was expressed, the element was immobile in the germline. This was not the case, however, in the soma of *A. aegypti* where *Hermes* excision and cut-and-paste transpositions were readily detected. Transposition events in the soma had all of the hallmarks of Class II cut-and-paste integration. Only those sequences precisely delimited by the ITRs moved and integration resulted in the creation of 8 bp direct duplications at the target site. Excision of *Hermes* was imprecise and led, in some cases, to the creation of small deletions. The basis for the difference in behavior of the *Hermes* element in the germline versus the somatic tissue of *A. aegypti* is unknown. Clearly the postintegration behavior of *Hermes* in this species will influence how this element will be employed, and in situations were germline stability is essential, *Hermes* will be particularly useful. It will not be useful in its present form for constructing gene-finding tools such as enhancer and promoter traps that rely heavily on transposable element vector remobilization to be effective.

4.13.5.1.6. Extrachromosomal forms of *Hermes* Excision of *Hermes* in *M. domestica*, and autonomous *Hermes* integrations in *D. melanogaster* and *A. aegypti*, lead to the formation of circularized *Hermes* elements in which the terminal inverted repeats are jointed end-to-end in various ways following the excision reaction (Atkinson and O'Brochta, unpublished data). The most common configuration results in the ends being joined end-to-end with a short spacer sequence between them. The spacer sequence was most often 1, 3, or 4 bp but could also be as much as 200 bp. The extrachromosomal *Hermes* elements found in *M. domestica* are particularly interesting because they have been found in all populations tested and in great abundance in somatic tissue. These data provide evidence for the somatic activity of *Hermes* in the insect from which it was originally isolated. Circularized forms of excised transposable elements of a number of types have been reported in the past (Sundraresan and Freeling, 1987). For example, circularized forms of *Ac/Ds* have been described as well as *Minos* (Arca *et al*., 1997; Gorbunova and Levy, 1997), yet the significance of extrachromosomal forms of transposable elements has remained unclear. In some cases the circularized elements do not contain intact ITRs and consequently the elements are not expected to be integration competent. Based on rather limited data it has generally been concluded that such forms represent byproducts of aborted or interrupted transposition reactions. A study of the extrachromosomal forms of *Hermes* suggests that these elements may have some biological significance. Circularized *Hermes* elements with intact ITRs are integration-competent, potentially allowing them to contribute to forward transposition (Atkinson and O'Brochta, unpublished data). The ability of circularized forms of excised *Hermes* elements to reintegrate may have an impact on the transmission potential of this element. The existence of a large pool of functional extrachromosomal transposable elements may have implications for the ability of the element to be transferred horizontally and may provide an additional means of vertical transmission (e.g., maternally inherited), both of which will potentially enhance the elements ability to increase in frequency within a population. The biology of extrachromosomal *Hermes* elements needs to be investigated further.

4.13.5.1.7. *hAT* elements have been found in other insects The Queensland fruit fly, *Bactrocera tryoni*, contains members of at least two distinct *hAT*-like transposable elements (Pinkerton *et al.*, 1999). *Homer* is a 3789 kb element whose sequence is 53% identical to *Hermes* and 54% identical to *hobo*. The transposase coding region is approximately 53% identical and 71% similar to the transposases of *Hermes* and *hobo*. Similarly, the ITRs of *Homer*, which are 12 bp in length, are identical to those of the *hobo* and *Hermes* elements at 10 of 12 positions. There are also *Homer*-like elements within *B. tryoni*. There are fewer than ten copies per genome, and while these elements have not been fully characterized, a conceptual translation of the transposase of this *Homer*-like element reveals 48% identity and 66% similarity to the transposase of *Homer*. These *Homer*-like elements are as similar to *hobo* as they are to *Homer*. Although *Homer* appears to be weakly functional in *D. melanogaster* based on plasmid-based excision assays, all *Homer*-like elements contain inactivating frameshift mutaions.

The blowfly *L. cuprina* contains a nonfunctional *hAT* element called *hermit*. *Hermit* was initially found by low stringency hybridization screening of an *L. cuprina* genomic library using a DNA probe homologous to *hobo* (Coates *et al.*, 1996). *Hermit* is 2716 bp and contains perfect 15 bp ITRs, the distal 12 of which are identical to the *hobo* ITRs at 10 of 12 positions. Although inactive because of frameshift mutations within the transposase coding region, its amino acid sequence is 42% identical and 64% similar to *hobo* transposase. *Hermit* is unusual in that it is present as a unique sequence within *L. cuprina*, in contrast to multiple copies that exist for most transposons. Although present only once within this species it does appear to have arisen within the genome as a result of transposition since the existing copy of the element is flanked by an 8 bp direct duplication of a sequence that is similar to the consensus target site duplication derived from other *hAT* elements. *Hermit* appears to have become inactivated soon after integrating into the *L. cuprina* genome.

Several *hAT* elements have been discovered in tephritid fruit flies using a polymerase chain reaction (PCR) approach similar to that used to discover *Hermes* (Handler and Gomez, 1996). Of these elements, a complete *hAT* transposon (*hopper*) was isolated from a genomic library of the wild Kahuku strain of the Oriental fruit fly, *B. dorsalis*, using the *B. dorsalis hobo*-related element (Bd-HRE) PCR product as a hybridization probe (Handler and Gomez, 1997). A complete 3120 kb element was isolated having 19 bp ITRs. However, the putative transposase-coding region was frameshifted and it did not have a duplicated 8 bp insertion site, suggesting that it had accumulated mutations and was nonfunctional. The Kahuku sequence was used to isolate additional *hopper* elements using an inverse and direct PCR approach, and a new 3131 bp *hopper* was isolated from the *B. dorsalis white eye* strain (Handler, 2003). This element has an uninterrupted coding region and an 8 bp duplicated insertion site. Notably, *hopper* is highly diverged from all other known insect *hAT* elements and its transposase is distantly yet equally related to the coding regions of *hobo* and *Ac*. Of the terminal 12 nucleotides only five are identical to those of *hobo*, while six are identical to the ITRs of *Homer* (*B. tryoni*). *hopper* also exists in the melonfly, *B. cucurbitae*, and another *hAT* element originally discovered in the melonfly, that is closely related to *hobo* and *Hermes*, also exists in *B. dorsalis* (Handler and Gomez, 1996).

hAT elements have been also reported in the human malaria vector *A. gambiae*. Approximately 25 copies of sequences that resemble *hAT* transposases were discovered although none appeared to be part of an intact transposable element. More recently, however, search criteria were used based on unique aspects of *hAT* transposable elements such as length and spacing of ITRs and the characteristics of *hAT* element target sites. This search revealed a *hAT* element in *A. gambiae* that contained perfect 12 bp ITRs flanked by 8 bp direct duplications and a 603 amino acid transposase open reading frame that appeared to contain no internal stop codons. This element (*Herves*) is most closely related to *hopper* and the ability of this element to excise and transpose in *A. gambiae* or other species has not been determined (Atkinson and Arenburger, personal communication).

4.13.5.2. *piggyBac*

4.13.5.2.1. Discovery of *piggyBac* and other TTAA-specific elements Similar to several other insect transposable element systems, the *piggyBac* element was discovered fortuitously in association with a mutant phenotype. However, unlike all the other transposons used for insect transformation, the mutant phenotype was the result of a functional element that had transposed into an infectious organism. Fraser and colleagues (see Fraser, 2000) discovered several Few Polyhedra (FP) mutations in the baculoviruses, *Autographa californica* nucleopolyhedrovirus (AcNPV), and *Galleria mellonella* nucleopolyhedrovirus (GmNPV), after passage through the *Trichoplusia ni* cell line TN-368 (Fraser *et al.*, 1983, 1985). Among these elements that inserted specifically into tetranucleotide TTAA sites

was *piggyBac* (then named IFP2), which transposed into AcNPV. Although it might be assumed that IFP2 was an autonomous functional element based on its mobility, another TTAA insertion-site element, *tagalong* (then called TFP3), discovered in AcNPV and GmNPV, was later found not to have a transposase coding region and thus had to be mobilized by another TFP3 or related element. Autonomous functional elements have not yet been found for *tagalong*, though the original IFP2 *piggyBac* element was indeed functional (Wang *et al.*, 1989; Wang and Fraser, 1993). All the *piggyBac* elements discovered in TN-368 were found to be identical, having a length of 2472 kb with 13 bp perfect ITRs and 19 bp subterminal repeats located 31 bp from the 5′ ITR and 3 bp from the 3′ ITR (Cary *et al.*, 1989) (**Figure 1**). The transposase coding region exists as a single reading frame of 2.1 kb that encodes a protein with a predicted molecular mass of 64 kDa. The functionality of *piggyBac* and the precise nature of its transposition was further verified by a series of viral and plasmid transposition and excision assays. A *piggyBac* indicator plasmid was marked with *polh/lacZ*, and assays in the fall armyworm, *Spodoptera frugiperda* cell line SF21AE showed that the original *piggyBac* element, within the p3E1.2 plasmid, could mobilize the marked element. These assays proved that the 3E1 *piggyBac* element encoded a functional transposase, and defined the element's TTAA insertion-site specificity and the precise nature of its transposition. Importantly, these assays also showed directly that *piggyBac* could be mobilized in other lepidopteran species (Fraser *et al.*, 1995), indicating that it might function similarly as a vector for germline transformation. This was a critical realization given the failure of *P* to be mobilized in non-drosophilids, which was consistent with its failure as a vector in these species.

4.13.5.2.2. *piggyBac* transformation The failure of *P* vectors to transform non-drosophilid species made the testing of other available transposon systems a high priority. The other systems found to be functional in non-drosophilids, however, were first tested successfully for gene transfer vector function in *Drosophila*. For *piggyBac*, germline transformation was first attempted in the Mediterranean fruit fly, *Ceratitis capitata*. This was possible due to the availability of a marker system that had been tested previously by medfly transformation with the *Minos* transposon vector. The medfly *white* gene cDNA was linked to the *Drosophila hsp70* promoter, and was used as a mutant-rescue system in a white eye host strain (Loukeris *et al.*, 1995b; Zwiebel *et al.*, 1995). In the absence of data for the minimal sequence requirements for *piggyBac* mobility, the first *piggyBac* vector was constructed by insertion of the 3.6 kb *hsp-white* cDNA marker into the unique *Hpa*I site within *piggyBac* in the p3E1.2 plasmid. None of the *piggyBac* sequence was deleted though the insertion interrupted the coding region eliminating transposase function. Construction of the first helper was a simple deletion of the 5′ ITR sequence resulting from a *Sac*I digestion and religation of p3E1.2. There is some uncertainty as to whether the upstream *Sac*I site cuts within the *piggyBac* promoter (Cary *et al.*, 1989), yet transposase expression was indeed sufficient to support germline transpositions from the vector plasmid. The first experiment with this helper in the medfly resulted in one transgenic line at a transformation frequency of 5% per fertile G_0. However, sibling sublines exhibited two and three independent integrations (Handler *et al.*, 1998). This experiment with a *piggyBac*-regulated helper was repeated with five additional G_1 lines isolated, but at approximately the same frequency. These attempts at *piggyBac* transformation yielded relatively low transformation frequencies, but it was notable that a lepidopteran transposon vector system had autonomous function in a dipteran species.

Subsequent to the medfly transformation, *piggyBac* transformation was tested in *Drosophila* using the mini-*white* marker from that species (Handler and Harrell, 1999). Using the self-regulated helper, transformants were isolated at a similar frequency of 1–3%, but tests with a *hsp70*-regulated transposase increased the frequency to above 25%, consistent with *P* and *hobo* transformations using heat shock promoted transposase.

Given that *piggyBac* was first isolated from a lepidopteran species, there was some optimism that it would be functional as a vector in other moth species. Function was first tested by transposition assays in the pink bollworn, *Pectinophora gossypiella* (Thibault *et al.*, 1999), which then led to successful germline transformation of this species using the phspBac helper and a vector marked with EGFP regulated by the *Bombyx actinA3* promoter (Peloquin *et al.*, 2000). Concurrent experiments were also performed in the silkmoth *B. mori* using a similar *actinA3*-regulated EGFP marker, but for this species transformation was achieved with an *actinA3*-regulated transposase helper (Tamura *et al.*, 2000). While these are the only moth species reported to be transformed with *piggyBac*, several other dipteran species have been transformed, as well as species in the orders Coleoptera and Hymenoptera. The dipteran species transformed include

several of medical and agricultural importance, such as the mosquitoes *Aedes aegypti* (Kokoza *et al*., 2001; Lobo *et al*., 2002), *A. gambiae* (Grossman *et al*., 2001), *A. albimanus* (Perera *et al*., 2002), and *A. stephensi* (Nolan *et al*., 2002), and the tephritid fruit flies *Anastrepha suspensa* (Handler and Harrell, 2000) and *Bactrocera dorsalis* (Handler and McCombs, 2000). Other transformed dipterans include *M. domestica* (Hediger *et al*., 2000) and *L. cuprina* (Heinrich *et al*., 2002). Of particular importance at this time, has been the use of *piggyBac* to transform a coleopteran, the red flour beetle, *Tribolium castaneum* (Berghammer *et al*., 1999; Lorenzen *et al*., 2003), and a hymenopteran, the sawfly *Athalia rosae* (Sumitani *et al*., 2003). Notably, all of these species were primarily transformed using a helper regulated by the *Drosophila hsp70* promoter, and with vectors marked with EGFP, though other fluorescent proteins have since been used for some as well.

Although most of these transformations occurred at frequencies between 3% and 5% per fertile G_0, dramatic differences between species have been observed as well, and in some of the same species performed by different laboratories. A single transformant line was reported for *Anopheles gambiae*, at a frequency of approximately 1% (Grossman *et al*., 2001), while transformation in *A. albimanus* occurred at frequencies ranging from 20% to 40% (Perera *et al*., 2002). The first transformations of *Tribolium* occurred at an unusually high frequency of 60% (Berghammer *et al*., 1999).

Many of the transformations were preceded by testing *piggyBac* function by embryonic transposition assays that were first developed for *piggyBac* mobility in the pink bollworm (Thibault *et al*., 1999). As discussed previously, these assays can rapidly assess the relative mobility of *piggyBac* in a specific host species in a few days. Positive results from these assays provided some assurance that more tedious and time-consuming transformation experiments had some likelihood of success. For some studies the assays also were used to test promoter function in helper plasmids, or provided insights into insertion site specificity, or determined the likelihood of a particular vector construct retaining function in the absence of specific sequences (Lobo *et al*., 2001). For example, *piggyBac* helper promoters were tested by transposition assays and germline transformation in *D. melanogaster* and *L. cuprina* (Li *et al*., 2001a; Heinrich *et al*., 2002). It was found that in *Drosophila*, an *hsp70*-regulated helper yielded the highest transposition frequency, while a constitutive *α1-tubulin*-regulated helper was more effective for germline transformation. By comparison, in *Lucilia* the *hsp70* helper was most effective for both plasmid and germline transpositions, while the *Drosophila α1-tub* helper failed to support transformation. Transposition assays have also shown target site preferences among the TTAA sites within the pGDV1 target plasmid, and assays in *Drosophila* indicated a bias for sites having A or T nucleotides at positions −3, −1, +1, and +3 relative to TTAA (Li *et al*., 2001a). However, a sequence analysis of 45 genomic integrations sites in *Tribolium*, after *piggyBac* vector remobilization, failed to show this bias (Lorenzen *et al*., 2003), which may be an indication of species specificity for insertion site preference.

Mobility assays also provide a rapid means of testing sequence requirements for vector mobility, which allow modifications for more efficient vector function. Since vector mobility is known to be affected negatively with increasing size, this information should allow minimal vectors to be created that retain optimal function. However, minimal sequence requirements for plasmid transpositions may differ from those for chromosomal transposition. For example, excision and transposition assays performed in *Trichoplusia ni* embryos showed that the *piggyBac* inverted terminal repeat and subterminal repeat sequences were sufficient for transposition (35 bp from the 5′ terminus and 63 bp from the 3′ terminus), but that an outside spacer region between the ITRs of greater than 40 bp is necessary for optimal transposition from a plasmid (Li *et al*., 2001b). Use of similar vectors in *Drosophila*, however, did not result in germline transformants (Handler, unpublished data). The minimal sequence requirements for *piggyBac* transformation verified thus far for *Drosophila* are 300 bp from the 5′ terminus and 250 bp from the 3′ terminus (Li, Fraser, and Handler, unpublished data).

4.13.5.2.3. Phylogenetic distribution of *piggyBac* and implications for transgene stability Unlike most other transposons used for transformation, *piggyBac* is not an apparent member of a larger family, or superfamily of related elements such as the *mariner*/*Tc* or *hAT* families. Until recently, the only *piggyBac* elements known were the functional elements orginally discovered in *T. ni* (Fraser *et al*., 1983). Thus, an unexpected finding from the Southern analysis of *B. dorsalis* transformants was that 8 to 10 *piggyBac*-related elements exist in the host strain genome (Handler and McCombs, 2000). PCR analysis of internal coding sequence indicated that these were nearly identical elements, though none has been found to be identical to *piggyBac*, nor are their coding regions consistent with transposase

functionality. The isolation of complete *B. dorsalis* *piggyBac* elements as genomic clones and by inverse PCR indicate that complete elements exist with conserved terminal and subterminal sequences that are integrated into duplicated TTAA insertion sites. *Bactrocera dorsalis* is part of a larger species complex and PCR analysis indicated that, indeed, *piggyBac* exists throughout the complex having nucleotide sequence identities of 92% among all the elements sequenced, with individual identities of 96–99% to one another and the *T. ni* 3E1 *piggyBac* (Handler, unpublished data).

4.13.5.2.4. *piggyBac* in other insects The evolutionary distance between *T. ni* and *Bactrocera* strongly suggests that the transposon moved between these species by recent horizontal transmission, and the separation of their geographical habitats raises the possibility that this movement may have been mediated by intermediary species. A Southern blot survey for *piggyBac* in more than 50 species showed the most clear evidence for multiple *piggyBac* elements in *S. frugiperda*, but hybridization patterns suggested that most of the elements are defective and nonfunctional (Handler, unpublished data; see Handler, 2002a). Evidence for *piggyBac* in other insects and other organisms, including mosquitoes and humans, comes from recent sequence data from genome projects. Although discrete sequence similarities suggests that *piggyBac* has an ancient history, there is little evidence at present to indicate that *piggyBacs* have coevolved as functional elements, and related complete elements have yet to be discovered.

The first functional *piggyBac* elements were discovered in a *T. ni* cell line, but little analysis has been done to characterize *piggyBac* in the organismal genome. Recent hybridization analysis of *piggyBac* from larval *T. ni* genomes indicates that *piggyBac* exists, and that its general structure is consistent with full-length functional elements. However, a PCR survey of these genomic sequences has only identified nonfunctional elements, having a level of identity no greater than many of the elements found in *Bactrocera* (>96%) (Zimowska and Handler, unpublished data). If functional *piggyBacs* do not exist *in vivo*, this could be explained by genomic instability that may arise from a highly active transposon. Functional elements may create a genetic load resulting in organismal lethality, which is more easily withstood in cell lines. If this is the case, it is therefore intriguing to consider how the functional element arose in the cell line.

It is also intriguing to consider how horizontal transmission of *piggyBac* may have occurred, considering that the element was originally discovered by virtue of its transposition into an infectious baculovirus. This could potentially explain a distribution among lepidopterans, but not the apparent recent movement between moths and flies. Understanding the interspecies movement of *piggyBac*, as well as all other vectors used for practical application, will be critical to undertanding and eliminating risk associated with the release of transgenic insects.

4.13.5.3. *mariner*

4.13.5.3.1. Discovery, description, and characteristics The *mariner* element was first discovered as an insertion element responsible for the *white*-peach (w^{pch}) mutant allele of *D. mauritiana* (Haymer and Marsh, 1986; Jacobson *et al.*, 1986). This particular allele was interesting when discovered because it was highly unstable with reversions to wild type occurring at a frequency of approximately 10^{-3} per gene per generation. *white*-peach individuals also had a high frequency of mosaic eyes, at an approximate frequency of 10^{-3}, suggesting somatic instability. Molecular analysis of the w^{pch} allele indicated that it was the result of a 1286 bp transposable element insertion into the 5′ untranslated leader region of the *white* gene (Jacobson *et al.*, 1986) (**Figure 1**). The *mariner* element is a Class II type transposable element with 28 bp imperfect inverted repeats with four mismatches. The element recovered from w^{pch} contained a single open reading frame capable of encoding a 346 amino acid polypeptide (Jacobson *et al.*, 1986). While the original w^{pch} was highly unstable, another strain of *D. mauritiana* was discovered in which mosaicism of the eyes occurred in every fly (Bryan *et al.*, 1987). This mosacism factor was found to be heritable and was referred to as *Mos1* (Mosaic eyes). *Mos1* was a dominant autosomal factor on chromosome 3 and was subsequently found to be identical to *mariner* except for six amino acid differences in the putative transposase coding region (Medhora *et al.*, 1988). *Mos1* encodes for a functional transposase while the 346 amino acid polypeptide of the w^{pch} *mariner* element was not a functional transposase.

One of the most notable characteristics of *mariner* and *mariner*-like elements (*MLE*s) is their widespread distribution. *MLE*s are found not only in insects and invertebrates but also in vertebrates and plants (Robertson, 2000; Robertson and Zumpano, 1997). Not long after the *D. mauritiana* *mariner* elements were described, a related element was discovered in the *cecropin* gene of the moth *Hyalophora cecropia* (Lidholm *et al.*, 1991). Based on the sequence comparison between the *mariner* elements from *D. mauritiana* and *H. cecropia*, Robertson (1993) designed degenerate PCR primers

and surveyed 404 species of insects for the presence of related sequences. He found that 64 of the genomes examined contained *MLE*s, and within this group are five subgroups referred to as the *mauritiana, cecropia, mellifera, irritans*, and *capitata* subgroups (Robertson and MacLeod, 1993). Since that original analysis insect *MLE*s have continued to be discovered and currently there are two additional subgroups recognized, known as *mori* and *briggsae* (Lampe *et al*., 2000). Additional subgroups are likely to be recognized in the future as additional representatives of this family of elements are found. Elements from different subgroups are typically about 50% identical at the nucleotide sequence level while the transposases encoded by elements from different subgroups are usually between 25% and 45% identical at the amino acid level. A notable feature of the phylogenetic relationships of the *MLE*s is their incongruence with the phylogenetic relationships of the insects from which they were isolated. The implication is that many of these elements were introduced into their host genome via a horizontal gene transfer event (Robertson and Lampe, 1995a). The abundant examples of horizontal transfer of *mariner* elements have led to the conclusion that such transfers occur relatively frequently. Hartl *et al*. (1997) estimated that the rate of horizontal transmission of *MLE*s is about the same as the rate of speciation, at least within the *D. melanogaster* species subgroup. The widespread occurrence of horizontal transmission of *MLE*s has been proposed to be critical for the long-term survival of these elements. Horizontal transmission provides a means for invading naive genomes where element proliferation can occur before inactivating influences of mutation and host regulation can occur (Hartl *et al*., 1997).

Although hundreds of *MLE*s have been reported, only two (*Mos1* from *D. mauritiana* and *Himar1* from *Haematobia irritans*) have been demonstrated to be functional or active. *Haemotobia irritans* contains approximately 17 000 copies of *Himar1*, although all of the copies examined were highly defective. Functional elements could be reconstructed based on the consensus sequence of *Himar1* and then constructed by modifying the closely related *Cpmar1* element from the green lacewing, *Chrysoperla plorabunda,* to match the *Himar* consensus sequence (Robertson and Lampe, 1995b; Lampe *et al*., 1998). Purification of the transposase from a bacterial expression system and its use in an *in vitro* mobility assay demonstrated the functionality of the *Himar1* protein and the ITRs of the element (Lampe *et al*., 1996).

4.13.5.3.2. Structure–function relationships The transposases of *MLE*s belong to a large group of integrases and transposases that share a significant feature of their catalytic domains. Specifically, *MLE*s contain the highly conserved DD35E motif within the active site of the protein (Robertson, 2000). This part of the active site interacts with a divalent cation that is essential for catalysis. Transposase binds to the ITRs of the element, and gel retardation assays were used to assess the binding activity of eight mutant transposases with deletions at the N- or C-termini (Auge-Gouillou *et al*., 2001a). It was possible to show that amino acids 1–141 were sufficient for binding to the ITRs. The ITR binding domain of *Mos1* transposase differs somewhat from that of *Tc1* elements in that it is composed of two different structural motifs, a helix–turn–helix motif and an α-helical region (Auge-Gouillou *et al*., 2001a).

The ITRs of *Mos1* are not identical and differ in sequence at four positions, which have effects on the activity of the element *in vitro*. Auge-Gouillou *et al*. (2001b) reported a 10-fold higher affinity of *Mos1* transposase for the 3′ ITR compared to the 5′ ITR. In addition, modified 5′ ITRs that were made to resemble 3′ ITRs at one of the four variable positions resulted in an increase in transposase binding. These investigators also showed that a *Mos1* element with two 3′ ITRs had 104 times the transposition activity of the native ITRs (Auge-Gouillou *et al*., 2001b). This hyperactive double-ended configuration has not been tested *in vivo*.

Hyperactive transposase mutants of the *Himar1* transposase have been reported (Lampe *et al*., 1999) and one of the mutants contains two amino acid changes (at positions 131 and 137) in the ITR binding domain of the protein. Although not tested directly, it is possible that these hyperactive mutants result in increased binding of the transposase and consequently higher rates of movement. Paradoxically, neither *Himar1* nor any of the hyperactive muatants shows any transpositional activity in insects (Lampe *et al*., 2000).

4.13.5.3.3. Host range of *mariner* The widespread distribution of *MLE*s in nature and the frequent examples of their horizontal transfer between species suggest that these elements have a broad host range. Empirical studies in which *Mos1* has been employed as a gene vector in a wide variety of organisms supports this conclusion. *Mos1* has been used successfully to create transgenic *D. melanogaster* (Lidholm *et al*., 1993), *D. virilis* (Lohe and Hartl, 1996a), and *Aedes aegypti* (Coates *et al*.,

1998). In each of these species the frequency of transformation was approximately 5%. This element has also been used to create transgenic *B. mori* cells in culture (Wang *et al*., 2000). In addition to transgenic insects, *Mos1* has been used to create transgenic *Leishmania* (Gueiros-Filho and Beverley, 1997), *Plasmodium* (Mamoun *et al*., 2000), zebrafish (Fadool *et al*., 1998), and chickens (Sherman *et al*., 1998). Similarly the *Himar1* element has been shown to function in *E. coli* (Rubin *et al*., 1999), Archaebacteria (Zhang *et al*., 2000), and human cells (Zhang *et al*., 1998). However, this element has not been shown to be active in *D. melanogaster* or any other insect species, for reasons that are not clear (Lampe *et al*., 2000).

4.13.5.3.4. Postintegration behavior The postintegration behavior of *Mos1* has been investigated in *D. melanogaster* and *A. aegypti*. *mariner* gene vectors used to create transgenic *D. melanogaster* have been found to be uncommonly stable even in the presence of functional transposase. Lidholm *et al*. (1993) created two lines of transgenic *D. melanogaster* with a *mariner* vector derived from *Mos1* and containing the mini-*white* gene as a genetic marker. When these lines were crossed to *Mos1* transposase-expressing lines, eye mosaicism was found in only 1% of the progeny, while these same *Mos1* expressing lines resulted in 100% mosaicism of the w^{pch} element. Similarly, germline transposition occurred at rates of less than 1% (Lidholm *et al*., 1993), and Lohe *et al*. (1995) reported similar evidence for postintegration stability of *mariner* vectors. Lozovsky *et al*. (2002) suggested, after investigating the postintegration mobility of a number of *mariner* vectors containing different genetic markers in different locations within the element, that *mariner* mobility is highly dependent upon critical spacing of subterminal sequences and ITRs. They found that vectors with simple insertions of exogenous DNA of varying lengths and in varying positions showed levels of somatic and germline excision that were at least 100-fold lower than that observed with uninterrupted *mariner* elements. Only vectors consisting of two, almost complete, elements flanking the marker gene showed detectable levels of both somatic and germline mobility. Approximately 10% of the insects with these composite vectors had mosaic eyes when transposase was present. Germline excision rates of approximately 0.04% were observed in these same insects. Again, these values are considerably less than those reported for uninterrupted elements. In addition to the potential importance of subterminal sequence spacing (Lozovsky *et al*., 2002), Lohe and Hartl (2002) suggested that efficient mobilization of *mariner in vivo* also depends on the presence of critical sequences located quite distant from the ITRs. Based on the mobility characteristics of about 20 *mariner* elements with a wide range of internal deletions, they concluded that there are three regions within the element that play an important role in *cis*. Region I is approximately 350 bp in length and is located 200 bp from the left 5′ ITR. Region II is approximately 50 bp in length and located approximately 500 bp from the right 3′ ITR. Region III is about 125 nucleotides in length and located approximately 200 bp from the right ITR (Lohe and Hartl, 2002). While the presence of subterminal sequences that play a critical role in the movement of many Class II transposable elements is not unusual, what is uncommon in the case of *mariner* is the location of these *cis*-critical sequences. Their dispersed distribution within the element is unique, and consequently, manipulating the element for the purposes of creating gene vectors and associated tools without disrupting these important relationships may be difficult.

The postintegration mobility of *Mos1* can also be regulated by nonstructural aspects of the system including “overproduction inhibition” and “dominant-negative complementation.” Increasing the copy number of *Mos1* in the genome resulted in a 25% decrease in the rate of germline excision. Copy number increases in *Mos1* presumably lead to increased transposase levels and, by an unknown mechanism, to the inhibition of excision (Lohe and Hartl, 1996b). High concentrations of transposase may lead to nonspecific associations of the protein resulting in inactive oligomers of transposase. In addition, the presence of mutated forms of *Mos1* transposase can repress the activity of functional transposase. Because the transposases of other transposable elements act as dimers or multimers it is thought that mutated *Mos1* transposases may become incorporated into multimers with functional transposases, thereby inactivating the entire complex (Lohe and Hartl, 1996b).

The possibility that transposase overproduction may negatively affect its own activity is a highly important concept in terms of vector system development. Most systems have the helper transposase under strong promoter regulation to optimize transpositional activity, though this may, indeed, be counterproductive. For *mariner* vectors, and potentially other systems, optimal transformation may require testing various helper promoters and a range of plasmid concentrations.

The postintegration mobility properties of *mariner* were also examined in *A. aegypti* (Wilson *et al*.,

2003). As part of an effort to create an enhancer trapping and gene discovery technology for *A. aegypti*, they created nonautonomous *mariner*-containing lines and lines expressing *Mos1* transposase. By creating heterozygotes between these two lines, they attempted to detect and recover germline transposition events, but only a single germline transposition event was recovered after screening 14 000 progeny. Somatic transpositions were detected, and while precise estimates of rates of somatic transposition were not possible because of the detection method, the authors observed fewer than one event per individual which they estimated to be an indication of a very low rate of movement. The vectors used by Wilson *et al*. (2003) resembled the simple vectors reported by Lozovsky *et al*. (2002) which had apparently disrupted spacing of the ITRs, and partial deletions of *cis*-critical sequences described by Lohe and Hartl (2002).

While the postintegration stability of *mariner* has been described in two species and appears to be a general mobility characteristic of this element, and not a reflection of a species-specific host effect, paradoxical observations remain to be explained. First, the use of *mariner* as a primary germline transformation vector in non-drosophilid insects and in non-insect systems is an effective means for creating transgenic organisms. Indeed, the host range of *mariner* as a gene transformation vector is unrivaled by any of the other gene vectors currently employed for insect transformation. *mariner* has been used as a gene vector in microbes, protozoans, insects, and vertebrates. The rates of germline transformation using *mariner*-based vectors in insects is approximately 10% or less, and is comparable to the efficiency of *Hermes*, *Minos*, and *piggyBac* gene vectors. This raises the question of whether *mariner* vectors present on plasmids behave the same as *mariner* vectors integrated into insect chromosomes. Given the rates of germline integration from plasmids it appears that the *mariner* vectors being used are not suffering from "critical spacing/critical sequence" defects. In addition, the *in vitro* behavior of *mariner* also differs from the behavior of chromosomally integrated elements. Tosi and Beverly (2000) demonstrated that only 64 nucleotides from the left end, and 33 nucleotides from the right end, of *mariner* were essential for transposition of a 1.1 kb vector *in vitro*. The rate of transposition of a minimal *mariner* vector *in vitro* was only two-fold less than that of a vector containing essentially a complete *mariner* element. These results suggest that *mariner* mobility has relatively simple sequence requirements and that the role of subterminal sequences is minimal *in vitro*. These apparently conflicting data suggest that host factors may play an important role in the transposition process *in vivo*, and may influence the relative importance of *cis* sequences in the *mariner* transposition process. The broad distribution of *MLE*s and host range of *mariner/Mos1* suggest, however, that host factors play little role in the movement of these elements.

The postintegration behavior of *mariner/Mos1* seems to indicate that this element will not be a good candidate for developing gene-finding tools such as promoter/enhancer trapping and transposon tagging systems in *A. aegypti* or perhaps other insects. On the other hand, if a high level of post-integration stability is desired, then *mariner* is an appropriate element to consider in insects. The potential of this element to be lost through excision or transposition is low, even in the presence of functional *mariner* transposase. As currently configured and used, *mariner* vectors may be considered as suicide vectors in insects since they essentially become dysfunctional upon integration.

4.13.5.3.5. *MLE*s have been found in other insects While hundreds of *MLE*s have been described, few have been shown to be functional. The original *mariner* element from the *white*-peach allele was transpositionally competent although it did not produce a functional transposase. *Mos1* is a functional autonomous element and has been the basis for constructing all *mariner* gene vectors that function in insects. *Himar1* is a functional element from the *irritans* subgroup that was reconstructed based on multiple sequence comparisons of elements within this group. It has not been shown to be functional in insects despite significant efforts to do so. Lampe *et al*. (2000) report that at least eight other elements from the other subgroups are likely to be active or made active by minor modifications.

4.13.5.4. *Minos*

The first germline transformation of a non-drosophilid insect mediated by a transposon-based vector system was achieved with the *Minos* element. *Minos* was originally isolated as a fortuitous discovery in *D. hydei* during the sequencing of the non-coding region of a ribosomal gene (Franz and Savakis, 1991). *Minos* was found to be a 1.4 kb element having, unlike the other Class II transposons used as vectors, relatively long ITRs of 255 bp, with its transcriptional unit consisting of two exons (**Figure 1**). Additional *Minos* elements were isolated from *D. hydei* having small variations of one or two nucleotides, though the new elements had a transition change that restored the normal reading frame allowing translation of a functional transposase.

The sequence homology, general structure, and TA insertion-site specificty placed *Minos* within the *Tc* transposon family (Franz *et al.*, 1994). *Minos* was first used to transform *D. melanogaster* with *Minos*-mediated events demonstrated by sequencing insertion sites and remobilization of integrations (Loukeris *et al.*, 1995a). The first non-drosophilid transformation with *Minos* was achieved in a medfly *white eye* host strain using a cDNA clone for the medfly *white* gene as a marker (Zwiebel *et al.*, 1995), at an approximate frequency of 1–3% per fertile G_0 (Loukeris *et al.*, 1995b). *Minos* transposition was subsequently demonstrated in dipteran and lepidopteran cell lines (Klinakis *et al.*, 2000; Catteruccia *et al.*, 2000a), with germline transformation reported for *Anopheles stephensi* (Catteruccia *et al.*, 2000b) and *D. virilis* (Megna and Cline, personal communication). Recently transformation frequencies have been substantialy increased in *Drosophila* and medfly by the use of *in vitro* synthesized transposase mRNA as helper (Kapetanaki *et al.*, 2002).

Although *Minos* has not been widely used for insect transformation, embryonic and cell line mobility assays in several insect species in the Diptera, Lepidoptera, and Orthoptera have indicated a broad range of function. Notably, *Minos* transposition in the cricket *Gryllus bimaculatus* was driven by transposase regulated by a *Gryllus* actin gene promoter, and not by the *Drosophila hsp70* promoter that has been widely used in dipterans (Zhang *et al.*, 2002). The broad function of the *Minos* vector is further supported by its ability to transpose in a mouse germline (Drabek *et al.*, 2003).

Minos structure places it within the *mariner*/*Tc* transposon superfamily, though knowledge of the distribution of *Minos* is thus far limited to the genus *Drosophila* (Arca and Savakis, 2000). In *Drosophila*, *Minos* is clearly widely distributed in the *Drosophila* and *Sophophora* subgenera, though discontinuously in the *Sophophora*. As noted for the *hAT*, *mariner*, and *piggyBac* elements, *Minos* may have also undergone horizontal transfer between *Drosophila* species.

4.13.5.5. *Tn5*

Tn5 is one of a number of very well-characterized transposable elements from prokaryotes. Recently, hyperactive forms of this element have been created in the laboratory that have proven to be the basis for the development of a number of commercially useful genomics tools (Goryshin and Reznikoff, 1998; Epicentre, 2004). *Tn5*-based genomics tools can be used in a wide variety of bacterial species and given the system's independence from host-encoded factors, might be applicable to eukaryotic systems as well (Goryshin *et al.*, 2000). Efforts to use *Tn5* as an insect gene vector have been successful.

Tn5 is a prokaryotic transposon 5.8 kb in length, and it is often referred to as a composite transposon because it consists of five independently functional units (review: Reznikoff, 2000) (**Figure 1**). It contains three antibiotic resistance genes that are flanked by 1.5 kb inverted repeat sequences. Each inverted repeat is actually a copy of an *IS50* insertion sequence that are themselves functional transposons. Each *IS50* element contains 19 bp terminal sequences known as outside end (OE) and inside end (IE), and while OE and IE are very similar, they are not identical. *IS50* also encodes for two proteins: transposase (Tnp) is 476 amino acids long and catalyzes transposition while the second protein is an inhibitor of transposition (Inh). The *IS50* elements present at each end of *Tn5* are not identical and only *IS50R* is fully functional. *IS50L* contains an ochre codon that prematurely terminates the Tnp and Inh proteins resulting in a loss of function of both proteins.

The transposition reaction and all of the components involved in the reaction have been studied in great detail (Reznikoff *et al.*, 1999). Transposition proceeds by a cut-and-paste process involving binding of Tnp to the end sequences followed by dimerization of the bound Tnp to form a synaptic complex. Cleavage at the ends of the element results in an excised transposon with bound transposase that interacts with a target DNA molecule. Strand transfer results in the integration of the element into the target, and *in vitro*, this reaction requires only a donor element, a target DNA molecule, transposase, and Mg^{2+} (Goryshin and Reznikoff, 1998). Modifications of both the transposase and the terminal 19 bp sequences have lead to the creation of *Tn5* elements consisting of little more than two copies of end sequences that can be mobilized a 1000-fold more efficiently than an unmodified *Tn5* element. This hyperactive *Tn5* system has been developed into a powerful tool for genetic analysis of a variety of organisms. *Tn5* has been attractive as a broad host range genomics tool because its pattern of integration is random and its biochemical requirements very simple. *Tn5* has been shown to function in a variety of bacterial and nonbacterial systems.

Current insect transformation protocols consist of microinjecting a mixture of two plasmids into preblastoderm embryos (see Section 4.13.6.3). One plasmid contains a nonautonomous transposable element with the transgenes and genetic markers of interest while the second plasmid contains a copy of the transposase gene. Transient expression of the

transposase gene is required postinjection and is followed by element excision and integration. Previous experiments examining the frequency of element excision of elements, such as *Hermes*, *mariner*, *Minos*, and *piggyBac*, from plasmids injected into insect embryos along with helper plasmids indicated that only one plasmid per thousand injected underwent an excision event. Therefore, 99.9% of the donor plasmids introduced into insect embryos will contribute nothing to the transformation efforts. The introduction of preexcised elements configured as active intermediates, such as synaptic complexes, was considered a means to permit higher integration rates and overall efficiency of transformation.

Transgenic *Aedes aegypti* were created using a *Tn5* vector containing DsRed under the regulatory control of the 3xP3 promoter (Rowan *et al*., 2004). Preexcised vectors in the form of synaptic complexes were injected into preblastoderm embryos. Nine hundred adults were obtained from the injected embryos and families consisting of approximately 10 G_0 individuals were established. Two families of G_0 individuals produced transgenic progeny for an estimated transformation frequency of 0.22% (2/900). Analysis of the transgenic progeny showed that multiple integrations of *Tn5* occurred in each line. The patterns of integrations were complex with evidence of the *Tn5* vector integrating into *Tn5* vector sequences. The integration of the vector into copies of itself followed by the integration of the resulting concatamers was very unusual, and in no case was a simple cut-and-paste integration of the *Tn5* vector found with characteristic 9 bp direct duplications flanking the element. The complex pattern of *Tn5* integration was thought to be a direct consequence of injecting preassembled intermediates, that were inactive in the absence of Mg^{2+}. Therefore, as soon as the synaptic complexes were injected they became activated and the first target sequences the elements were likely to encounter were other *Tn5* synaptic complexes. At the time of injection, *A. aegypti* embryos only contain approximately four to eight nuclei making genomic target DNA relatively rare. Furthermore, the synaptic complexes injected were expected to have a very short half-life. Therefore, although active intermediates were being introduced, a number of factors contributed to the inefficiency observed with this system including a short half-life of the active intermediate and low numbers of genomic target sequences. Injecting binary plasmid systems (as is done with *Hermes*, *mariner*, *Minos*, and *piggyBac*), while relatively inefficient in producing active transposition intermediates, achieves persistence over an extended period of time. Consequently, more target genomes are exposed to active vectors over a longer period of time, resulting in higher transformation rates. The limitations of injecting synaptic complexes is unlikely to be specific to the *Tn5* system and similar approaches with other insect gene vectors are likely to encounter similar problems. It should be noted, however, that the results of Rowan *et al*. (2004) demonstrate that *Tn5* is functional in insects and, while injecting active intermediates is not recommended, using *Tn5* in a more conventional binary plasmid system consisting of a donor and helper plasmids is likely to be a viable option for creating transgenic insects.

4.13.6. Transformation Methodology

The technical methodology for insect transformation has largely remained the same or only slightly modified from the techniques originally used to transform *Drosophila*. The references cited for *P* transformation are relevant to this, as well as several recent articles that focus on methods for non-drosophilid transformation (Handler and O'Brochta, 1991; Morris, 1997; Ashburner *et al*., 1998; Handler, 2000; Handler and James, 2000). The most variable aspect of this method is the preparation of embryos for DNA microinjection, though arguably, the lack of new techniques for DNA introduction has been the primary limitation in the more widespread use of the technology. While all successful insect transformations have utilized microinjection, variations on this method have been necessary for different types of embryos, and most of the procedures must be tested empirically and modified for particular insect species. This may be extended to different strains and for a variety of local ambient conditions including temperature and humidity. The apparatus for microinjection is usually the same for all species, though a wide variety of variations and modifications are possible and sometimes required. The basic equipment includes an inverted microscope or a stereozoom microscope with a mechanical stage having a magnification up to 60 to 80×; a micromanipulator that is adjustable in three axes with an appropriate needle holder; and a means to transmit the DNA into the egg. For dechorionated eggs, transmitted light allows precise positioning of the needle within the egg posterior, while direct illumination is needed for nondechorionated eggs that typically include mosquitoes and moths.

The standard for gene transfer methodology in general, and embryo microinjection in particular, was originally developed for *Drosophila*. The standard method involves collecting preblastoderm embryos

within 30 min of oviposition, and dechorionating them either manually or chemically. The timing of egg collection and DNA injection is related to the need to inject into preblastoderm embryos during a phase of nuclear divisions previous to cellularization. This allows the injected DNA to be taken up into the nuclei, and specifically into the primordial germ cell nuclei that are the gamete progenitors. For *Drosophila*, cellularization of the pole cells begins at approximately 90 min after fertilization at 25 °C, with blastoderm formation occurring about 30 min afterwards. The timing of these events and location of the pole cells varies among insects, and thus some knowledge of early embryogenesis in the desired host insect is highly advantageous. In the absence of this information for a particular species, the most prudent time of injection would be the earliest time after oviposition that does not compromise viability.

4.13.6.1. Embryo Preparation

Manual dechorionation of *Drosophila* eggs is achieved by gently rolling the eggs on double-stick tape with a forcep until the chorions peel off. While gentle on the eggs and requiring little desiccation time, manual dechorionation is tedious and has not been applicable to any other insect. Chemical dechorionation is typically achieved by soaking eggs in a 50% bleach solution (2.5% hypochlorite) for 2–4 min and washing at least three times in 0.02% Triton X-100. Tephritid fruit fly eggs usually have thinner chorions that can be dechorionated in 30% bleach (1.25% hypochlorite) in 2–3 min, but this must be determined empirically since they are easily overbleached resulting in death, either directly or after injection. Some species, such as *M. domestica*, can be only partially dechorionated, but bleached eggs can be released from the chorion by agitation. We have found the simplest and most precise method for bleach dechorionation with rapid washes is by using a 42 mm Buchner funnel with a filter flask attached to a water vacuum. Eggs can be washed into the funnel on filter paper and swirled within the funnel with the solution gently sucked out by regulating the water flow or the seal between the funnel and flask. The last wash is done on black filter paper that allows the eggs to be easily detected, which facilitates their mounting for injection (see below).

Many insects eggs cannot be dechorionated without a high level of lethality, and must be injected without dechorionation. These include most moth and mosquito species. *Drosophila* and tephritid flies can, similarly, be injected without dechorionation, and while embryo viability after injection is often lower than for dechorionated eggs, the frequency of transformation in surviving embryos is often higher. It is more difficult to determine a precise site for injection in nondechorionated eggs, though this can be aided by adding food coloring to the DNA injection mix.

After dechorionation, fruit fly embryos are typically placed on a thin strip (~1 mm) of double stick tape placed on a microscope slide or 22 × 30 mm cover slip, though use of a cover slip is more adaptable for subsequent operations. A thin strip of tape is suggested due to anecdotal reports of toxic solvents from the tape affecting survival, though some particular tapes are considered to be nontoxic (3M Double Coated Tape 415; 3M, St. Paul, MN, USA) and some are useful for particular applications such as aqueous conditions needed for mosquito eggs. Adhesives resistant to moisture include Toupee tape (TopStick™, Vapon Inc.) and Tegaderm (3M). When eggs are injected under oil, the tape strip is placed within a thick rectangle created with a wax pencil that can retain the oil. It is important that the wax fence not be breached by oil when overlaying the eggs, since the loss of oil will result in embryo death.

Where possible, eggs are placed on the tape in an orientation having their posterior ends facing outwards towards the needle, but at a slight angle. All fruit fly eggs must be desiccated to some extent before injection. The interior of the egg is normally under positive pressure, and yolk and injected DNA will invariably flow out after injection without desiccation. This will result in lethality, sterility (from loss of pole plasm), or the lack of transformation if the plasmid DNA is lost. The time and type of desiccation, however, must be evaluated empirically, and sometimes varied during the course of an injection period. A major factor for dechorionated eggs is the length of time they are kept on moist filter paper before being placed on the tape. Typically we desiccate embryos on one strip of tape (15–20 embryos) for 8 to 10 min. Depending on the ease of injection the time can be varied by 1–2 min. In ambient conditions that are humid, it may be necessary to desiccate in a closed chamber with a drying agent (e.g., drierite), with or without a gentle vacuum. An important consideration is that a very short variation in the time for desiccation can be the difference between perfect desiccation and overdesiccation resulting in death, and that the optimal desiccation time will vary for different eggs on the tape. Thus, it is unlikely that all the eggs will respond well to the set conditions, which must be modified so that the majority of eggs can be injected with DNA at a high level of survival and fertility. After the determined time for desiccation, the eggs

must be placed immediately under Halocarbon 700 oil, or oil of similar density, to stop the desiccation process. Desiccation of most nondechorionated eggs is more challenging and one approach is to soak eggs in 1 M NaCl for several minutes. In contrast, for nondechorionated mosquito eggs, desiccation can occur within 1–2 min after removal from water, which is evidenced by slight dimpling of the egg surface, and this must be observed to avoid overdesiccation. Due to the rapidity of desiccation, mosquito eggs are typically arranged on moist filter paper and blotted together onto a taped cover slip from above, and after desiccation, the eggs are submerged in Halocarbon oil. Nondechorionated eggs from many species do not require oil, and it may be lethal for some insects such as moths, yet oil submersion was helpful for the survival of *Drosophila* and tephritid flies.

4.13.6.2. Needles

The type of needle and its preparation is possibly the most important component of successful embryo injections. Most dechorionated fruit fly eggs can be injected easily with borosilicate needles, which are drawn out to a fine tip and broken off to a 1 to 2 μm opening. Opening the tip is typically achieved by scraping the needle against the edge of the slide carrying the eggs to be injected. Opening the needle by beveling, however, creates consistently sharp tips that are much more important for nondechorionated eggs, and stronger alumina-silicate and quartz needles also provide an improvement to easily pierce chorions or tough vitelline membranes. Beveled needles are also critical when a large tip opening is required for large plasmids that are susceptible to shearing. Preparation of borosilicate needles, pulled from 25 μl capillary stock that has been silanized, can be achieved with several types of vertical or horizontal needle pullers, and we find the Sutter Model P-30 (Sutter Instruments, Novato, CA, USA) vertical micropipette puller to be highly effective. Alumina-silicate needles, and certainly quartz needles, require more sophisticated pullers that allow for fine programmable adjustment of high filament temperatures and pulling force, and the Sutter Models P-97 and P-2000 fulfill this need. Several needle bevelers are available, with the Sutter BV-10 used by many laboratories.

4.13.6.3. DNA Preparation and Injection

A mixture of highly purified vector and helper plasmid DNA is essential to embryo survival. This is achieved most optimally by purifying plasmid twice through cesium chloride gradients or a solid-phase anion exchange chromatography column. These have the advantage of high yields of DNA, but the disadvantage of specialized equipment and long preparation times. Successful transformation has been achieved with plasmids prepared with silica-gel membrane kits from Qiagen Corp. (Valencia, CA, USA), but their successful use has been inconsistent, with failures possibly related to the type of host bacteria and its growth conditions. The Qiagen Endotoxin-free plasmid preparation systems allow additional purity, and this system is routinely used for successful plasmid injection.

Purified plasmid concentration must be titered accurately and verified by gel electrophoresis previous to injection mix preparation. Appropriate amounts of vector and helper plasmid are ethanol precipitated, washed several times in 70% ethanol, and resuspended in injection buffer. Injection buffer has typically been the same as that originally used for *Drosophila* (5 mM KCl, 0.1 mM sodium phosphate, pH 6.8), though this may not be optimal for other insects and embryo survival should be assessed by control injections. Total DNA concentration for injection should not exceed 1 mg ml^{-1}, using two- to fourfold higher concentration of vector to helper (e.g., 600 ng μl^{-1} vector to 200 ng μl^{-1} helper). Higher DNA concentrations are inadvisable since they are subject to shearing during injection and may clog the needle, and the nucleic acids and/or contaminants can be toxic to the embryo. High transposase levels may also have a negative effect on transposition, as with the overproduction–inhibition phenomenon observed with *mariner* (Lohe and Hartl, 1996b).

Previous to injection the DNA mixture should be filtered through a 0.45 μm membrane, or centrifuged before loading into the injection needle. Typically, DNA is back-filled into the injection needle using a drawn-out silanized 100 μl microcapillary, and a microliter of DNA should be sufficient for injecting hundreds of eggs.

4.13.6.3.1. DNA injection The microinjection of DNA into embryos requires a system that forces a minute amount of DNA through the needle in a highly controllable fashion. Remarkably, many *Drosophila* laboratories simply use a mounted syringe and tubing filled with oil connected to a needle holder, with manual pressure applied. This system is successful due to accumulated expertise and the efficiency of transformation in the species, but would probably be less useful for injecting more sensitive embryos that transform less easily. Regulated air-pressure systems are available that are economical and allow highly controlled and rapid DNA injection. We use the PicoPump from WPI that

is most versatile in allowing positive and negative (with vacuum) pressure, and a hold capability that prevents back flow into the needle resulting in clogging (especially by yolk). A less expensive system can be constructed from Clippard components (Clippard Instrument Laboratory, Inc., Cincinnati, OH, USA) that uses a simple air-pressure regulator and electronic valve and switch (see Handler, 2000). Needle holders from WPI can be used with both systems (MPH-3 and MPH-1, respectively).

All embryo injections are performed on a microscope with a mechanical stage, with the injection needle mounted on a micromanipulator. Microscopes first used for *Drosophila* transformation were inverted or compound microscopes, but the availability of a useful mechanical stage and stage adaptor for the Olympus SZ stereozoom microscopes makes this the most versatile choice (the Olympus stage can be mounted on most stereomicroscopes). The micromanipulator can be free-standing next to the stage or mounted on the microscope base. It allows the precise positioning of the needle at the desired point of entry into the egg, while the actual injection occurs by using the mechanical stage to push the egg onto the needle. Piezo Translators that were developed for rapid and automatic intracellular injection may be more efficient for some embryos, and will obviate the need for a mechanical stage (Peloquin *et al*., 1997). The WPI MPM20 translator used with the PV820 PicoPump allows a fully automated system for egg penetration, DNA injection, and needle withdrawal.

4.13.6.4. Postinjection Treatment

After injection the cover slip can be placed in a covered petri dish (but not sealed) with moist filter paper. The use of square dishes with black filter paper seems to be most suitable for up to six cover slips and simple observation of the embryos and hatched larvae. For injected embryos submerged in oil, oxygen concentration may be a limiting factor for development, if not viability. This can be ameliorated by reducing the crowding of eggs on the cover slip, or by incubation in a portable hatbox tissue culture chamber that is humidified and under slight positive pressure with oxygen. For eggs without oil, oxygen saturation without pressure is advisable.

Most helper constructs have the transposase gene under heat shock regulation. The *Drosophila hsp70* promoter is a constitutive promoter that is active in the absence of heat shock (but also responds to anoxia which may occur in embryos under oil), and transformation is possible with most vectors with or without heat shock treatment. If heat shock is desirable, it should be noted that the optimal temperature varies for different species. For example, *hsp70* responds optimally at 37 °C in *Drosophila*, but at 39 °C in medfly (Papadimitriou *et al*., 1998). Injected embryos should be incubated for at least 4–6 h after injection before heat shock, or after overnight incubation. Optimal temperatures for insect development vary, but the lowest temperatures possible can be beneficial to survival, and the injection process can slow development by 50% or more. Thus, larval hatching may be delayed considerably and hatching should be monitored for several days after the expected time before discarding embryos.

Hatched larvae can be placed on normal culture media, though they may be weak and require careful handling and soft diet. Rearing of putative transgenic lines is typically achieved by backcrossing to the parental line in small group matings, or individual mating if a determination of transformation frequency is required. Inbreeding of G_0s can minimize rearing efforts, but this may be complicated by high rates of infertility which is typically close to 50% after fruit fly injections.

4.13.7. Research Needs for Improved Transgenesis

4.13.7.1. DNA Delivery

Dramatic progress has been made in transformation technology for non-drosophilid insects, and it appears that the vectors and markers in use should be widely applicable. Nevertheless, transformation of many other insect species will be highly challenging, primarily due to limitations in the delivery of DNA into preblastoderm embryos. As noted, to date all successful non-drosophilid transformations have resulted from embryonic microinjection of DNA, but for many species current injection techniques are likely to result in high levels of lethality or sterility. Experimentation with alternative methods has been reported, though arguably, none has been tested exhaustively for germline transformation, or vector systems were used that are now known to be ineffective. The most promising method is biolistics where eggs are bombarded with micropellets encapsulated by DNA, which was first developed as a ballistics method to transform plant cells (Klein *et al*., 1987). Ballistics is based upon a “shotgun” technique for bombardment, and it is the only non-injection method successfully used to transform an insect. This was a *P* transformation of *Drosophila*, though only a single transformant line was created

and the technique never gained wide applicability (Baldarelli and Lengyel, 1990). This was most likely due to the high efficiency of *P* transformation of *Drosophila* by microinjection, eliminating the need for an alternative technique. Mosquito eggs are considerably more difficult to inject, and a significant effort was made to modify a biolistics approach to DNA delivery in *A. gambiae*, using a burst of pressurized helium for bombardments (Miahle and Miller, 1994). This technique was effective in introducing plasmid DNA into mosquito eggs, yielding high levels of transient expression of a reporter gene. Biolistics was subsequently used for transient expression in specific tissues, allowing the testing of fibroin gene promoters in the *B. mori* silk gland (Horard *et al.*, 1994; Kravariti *et al.*, 2001). Recent advances have included the use of a rigid macrocarrier in the Bio-Rad PDS/1000-Helium biolistics apparatus, which minimizes the blast effect in soft tissue (Thomas *et al.*, 2001). This allows greater micropellet penetration into insect tissues with improved survival. Despite these advances in delivering DNA into eggs and tissue, biolistics has yet to yield a germline transformant.

The only other method reported for DNA delivery is electroporation, which, like biolistics, has resulted in high levels of transient expression of plasmid-encoded genes in *Drosophila* (Kamdar *et al.*, 1992), as well as in *Helicoverpa zea* and *M. domestica* (Leopold *et al.*, 1996). Though transformation has not been reported, as with biolistics, it is not apparent that this was seriously tested or if functional vectors systems were used (certainly for non-drosophilids). Electroporation techniques have also advanced in recent years, with DNA transferred into many different tissue types from a variety of organisms using new electroporation chamber designs and electric field paramenters.

These recent advances with both biolistics and electroporation are highly encouraging that new efforts will have greater chances for success, and they deserve a high priority for testing. Both methods also have the advantage, if successful, of delivering DNA simultaneously to multiple embryos, ranging from hundreds to thousands depending on the species. This would be highly beneficial to all transformation experiments, but especially so for species that transform at low frequencies. These methods could also be used in cellularized embryos after blastoderm formation in insects having embryos that cannot be handled easily or collected in the preblastoderm stage.

Other approaches to DNA delivery can include the incorporation of vector/helper DNA into bacterial or viral carriers, that may be delivered by maternal injection or feeding. Variations on microinjection that might be required for ovoviviparous insects include maternal injection into ovaries or abdominal hemocoel (Presnail and Hoy, 1994), and the use of liposomes might allow injection into cellularized embryos (Felgner *et al.*, 1987). All of these techniques should be reevaluated with the use of vectors and markers now known to be highly efficient in non-drosophilid systems.

4.13.7.2. Gene Targeting

The ability to target genes to specific or desired integration sites in the genome would be highly advantageous to the basic and applied uses of transgenic strains. The expression of transgenes in most vector integrations is affected negatively by chromosomal position effects, so target sites known to be devoid of, or insulated from, suppression elements could be utilized for optimal or consistent transgene expression. Target sites positioned in innocuous genomic regions could also eliminate random integrations into genes necessary for viability and fertility, eliminating costs to fitness in host strains. It will also be highly important to gene expression studies to achieve reliable methods for gene replacement or targeted transposition, which is especially important for systems where preexisting null mutations, or gene "knockouts," do not exist.

Gene targeting can be achieved, generally, in two ways. First is homologous recombination where an endogenous genomic sequence is replaced by recombination with homologous sequences within or surrounding the transgene. This results in targeted transposition which can be used for gene replacement, or for targeting to an innocuous genomic region. This approach has been effective in transforming lower eukaryotes, and plant and vertebrate systems (see Bollag *et al.*, 1989) and has been reported to occur in *Drosophila* (Cherbas and Cherbas, 1997) and mosquito (Eggleston and Zhao, 2000) cell line studies. Homologous recombination can also occur in insects *in vivo*, but this is not routine and thus far, must be facilitated. In *B. mori*, female moths were infected with a modified AcNPV baculovirus that had its polyhedrin gene replaced with fibroin light chain-GFP gene fusion (Yamao *et al.*, 1999). Progeny of the infected moths exhibited stable integration of the gene fusion into the genomic fibroin gene, with resulting GFP expression. This particular method relies on host susceptibility to baculovirus infection, though conceivably other pantropic or species-specific viruses could be used for a wider range of insects.

Homologous recombination was also achieved in *Drosophila* where linearized extrachromosomal

DNA was found to be recombinogenic with homologous sequences in the genome (Rong and Golic, 2000). This was achieved by using the *FRT*–FLP recombination system to create DNA circles, which were linearized at a rare endonuclease recognition site within the *FRT* sequences, resulting in a *yellow* marker gene integrating into its homologous chromosomal site. This system has potential application in any insect species that can be stably transformed, but it requires the integration of three components which can be tedious to achieve and may present fitness costs to the host. Though its use could have major importance to genetic studies in non-drosophilid insects, thus far it is not routinely used in *Drosophila*.

4.13.7.2.1. Site-specific recombination Site-specific recombination systems such as the *FRT*–FLP system from the 2 μm circle of yeast (Senecoff *et al.*, 1985) mentioned above, and the bacteriophage Cre/*lox* system (Hoess *et al.*, 1985) can be used for various types of gene targeting and chromosomal manipulation. Both systems function in *Drosophila* in which recombination occurs between specific sequences in the presence of a recombinase enzyme (Golic and Lindquist, 1989; Siegal and Hartl, 1996). For *FRT*, the recombination site consists of two 13 bp inverted repeats separated by an 8 bp spacer that specifically recombines with identical *FRT* sites in the presence of FLP recombinase. Depending upon the orientation of the *FRT* sites, the intervening sequence between them can be inverted or deleted by recombination (Golic and Golic, 1996; Golic *et al.*, 1997). When placed within a vector, such *FRT* rearrangements can allow several types of vector manipulation after genomic integration. Genes or sequences within the vector necessary for the initial transformation or selection, but deleterious to use of the transformed strain, can be deleted or inactivated (Dale and Ow, 1991; see Handler, 2002b). This may include the marker system used for selection (e.g., chemical resistance system) or even a transposase gene used in a single plasmid autonomous vector system. Expression of genes of interest can be similarly manipulated by placing *FRT* sites outside the gene and within an internal noncoding region. Of particular importance to transgene stability would be the rearrangement of vector sequences required for mobility, that typically would include the terminal and subterminal ITRs. If *FRT* site placement between the terminal sequences does not hinder the primary transposon vector integration, then subsequent subterminal ITR deletion could eliminate any secondary vector mobilization. Such mobilization or cross-mobilziation would have serious consequences for strain stability and function, as well as ecological risks due to unintended transmission of the vector into other organisms. Eliminating this possibility would provide a major advancement to the applied use of transgenic insects.

The ultimate use of recombination systems for improved transformant stability and transgene expression would be their development into a second generation of vectors that use an integrated recombination site as a stable chromosomal target. Plasmids having the same recombination site and a marker gene would be used as vectors that integrate by recombination in the presence of recombinase. The expectation is that these systems would be highly stable in eukaryotes, and specific target site loci could be selected that are minimally affected by position effect variegation/suppression. The internal 8 bp spacer sequence within the *FRT* can be varied, but only identical *FRT* sequences will recombine with one another. Thus, multiple independent *FRT* target sites can be incorporated into the same genome. Importantly, manipulations by *FRT* recombination will depend upon a controllable source of FLP recombinase, which can be provided as a separate transgene integration, or exogenously by DNA, RNA, or protein injection.

4.13.8. Summary

After concerted efforts for more than 30 years to achieve gene transfer in non-drosophilid insects, only in the last decade have these efforts been fruitful. Since 1995 the germline of nearly 20 species in four orders of insects have been transformed, and this number may be only limited by the insects of current experimental and applied interest. Unlike plant and vertebrate animal systems that allow relatively efficient genomic integration of introduced DNA, insect systems have generally relied on vector-mediated integrations, and the only vectors found reliable for germline transformation are those based on transposable elements. Curiously, the two main vector systems developed for routine use in *D. melanogaster*, and originally discovered in that species, *P* and *hobo*, have not been applicable as vectors to any other species. Yet, four other transposons found in non-*melanogaster* or non-drosophilid species are widely functional in insects, and for some, other organisms. Their discovery has been of enormous importance to the wider use of transformation technology, since little progress would have been made if most vector systems were specific to a particular host. Equal in importance to the advancements in vector development, have been concurrent progress in genetic marker discovery and development. This began with the finding

that cloned eye color genes from *Drosophila* could complement existing mutations in other insects, and has continued with the more recent use of several fluorescent protein genes that are widely applicable as markers for transformation and reporters for gene expression.

The advancement of these techniques comes at a fortuitous time when genomics is providing a wealth of genetic infomation and resources that might be used to create transgenic strains of pest and beneficial insects to control their population size and behavior. As part of these efforts, genetic transformation is also critical to functional genomics studies that will provide information essential to understanding the biological function of genetic material, and relating specific genomic elements to those functions. Techniques such as enhancer traps and transposon tagging, which rely on remobilizable insertional mutagenesis, are only possible with transposon-based vector systems, and other techniques such as RNA interference (RNAi) are greatly facilitated by these systems. Together, routine methods for transposon-mediated germline transformation and genomics analysis should provide the tools for dramatic progress in our understanding and control of insect species.

4.14 Insect Cell Culture and Recombinant Protein Expression Systems

P J Farrell, The University of Calgary, Canada
L Swevers and K Iatrou, Institute of Biology, National Centre for Scientific Research ''Demokritos'', Athens, Greece

4.14.1. Introduction

In the era of genomics, proteomics, and biotechnology, protein expression systems play key roles. For example, characterization of a gene now requires overexpression of the encoded protein by heterologous expression systems to realize its functional and structural characterization. Furthermore, production of proteins for therapeutic purposes is dependent on the use of host organisms that are genetically engineered for protein production at high levels.

Several host organisms have been used in recent years for recombinant protein expression purposes. These include bacteria, yeast, mammals, and insects, as well as cell lines derived from various mammalian and insect species. Each of these expression systems has unique advantages and deficiencies and, as a result, is more suitable than the others for specific applications while not as good for others.

Bacterial expression systems, for example, can direct very high levels of protein expression but the recombinant proteins generally lack the posttranslational modifications that take place in eukaryotes. Thus, for eukaryotic proteins that require appropriate modifications for functionality, bacterial expression systems are considered inappropriate. Bacteria also do not have eukaryotic-type secretion systems and normally secreted heterologous proteins usually accumulate in the bacterial cytoplasm in the form of insoluble aggregates, known as "inclusion bodies," which make the purification of functional proteins extremely difficult.

Yeast-based expression systems can normally yield high levels of recombinant proteins. However, the expression levels for particular classes of proteins such as secreted or membrane-anchored proteins are, in general, much more limited than those for intracellular proteins. Moreover, the patterns of posttranslational modifications including glycosylation are more limited in yeast than in higher eukaryotes and this limitation often affects biological activity.

Transformed mammalian cells are considered to represent excellent means for expression of membrane-anchored and secreted proteins. However,

mammalian cells need to be maintained in expensive media supplemented with CO_2 under carefully controlled conditions. Most importantly, mammalian cell lines are also potential sources of harmful pathogens, which can limit their utility for production of proteins of pharmaceutical value. Finally, mammalian systems are labor intensive because it requires several months for the generation of clones overexpressing stably recombinant proteins.

Insect cell-based expression systems, which can be used for *in vitro* production of virtually all types of heterologous proteins, accumulate most of the advantages of the other expression systems while lacking most of their disadvantages. Insect cell-derived expression systems are currently divided into two types, (1) the baculovirus expression system, which employs insect cell lines as hosts for baculovirus expression vectors and recombinant protein production in batch mode, and (2) transformed insect cell lines that overexpress continuously proteins from nonlytic plasmid-based expression vectors.

Following the development of the Baculovirus Expression System (BES) in 1983, insect cells have been employed extensively for the production of a wide variety of recombinant proteins using various versions of baculovirus-based expression vectors, and excellent results have been obtained for various research and industrial applications. As a result, the baculovirus/insect cell expression system is currently considered as the industry workhorse for recombinant protein production. As explained below, however, an important limitation of this system relates to the production of secreted proteins and proteins that require extensive posttranslational modifications. Furthermore, the baculovirus expression system is a transient production system because host cells are lysed and killed during each infection cycle.

More recently, a series of baculovirus-free expression vector systems have also emerged, which direct high-level recombinant protein production in insect cell lines, either simply transfected or stably transformed with relevant expression plasmid DNAs, and circumvent the disadvantages of the baculovirus expression system. These insect cell-based expression systems can be divided into two subgroups, one employing dipteran insect cell lines and another that utilizes lepidopteran insect cell lines. For the latter, the incorporation of genetic elements obtained from baculoviruses in the context of plasmid vectors has allowed the generation of extremely powerful expression vectors that direct the generation of large quantities of recombinant proteins. In general, continuous insect cell-based expression systems show outstanding features for the production of recombinant proteins, which, among others, include:

1. A fast process from cDNA cloning to production of recombinant protein – stable cell lines expressing recombinant protein are developed within 1–2 months.
2. High yields of secreted recombinant proteins that may surpass those achieved by the baculovirus system and mammalian cell systems.
3. Utilization of cell lines derived from a multitude of insect species.
4. Easy purification of secreted proteins from serum-free media.
5. Full capacity of posttranslational modifications – the cells maintain their integrity throughout the production process.
6. Continuous protein production – the transgene is stably integrated into the genome of the cells and protein production occurs continuously because no lysis occurs.

Irrespective of whether it is associated with the use of baculovirus or plasmid expression vectors, the use of insect cells can overcome the shortcomings of other established protein expression workhorses. Among others, the advantages of insect cells over other expression systems include the capacity to produce higher levels of soluble recombinant proteins that are folded correctly and extensively modified posttranslationally, the fact that both baculoviruses and insect cell lines are nonpathogenic to humans, and that insect cells can be grown in medium free of protein or other, potentially pathogenic, animal products.

This article is intended as a practical review of the developments in both baculovirus and plasmid-based protein expression systems employing insect cells. New applications of insect cells are also discussed including surface display and high-throughput screening for the identification of bioactive compounds. For related information on this topic, particularly in relation to applications related to baculoviruses and expression systems derived from them, the reader is also referred to **Chapters 6.8** and **6.9**.

4.14.2. Baculovirus Expression Systems

4.14.2.1. Brief History of the Baculovirus Expression System

Insect cells have certainly gained most of their popularity as hosts for production of foreign proteins using recombinant baculoviruses as expression vectors. For this application, the Open Reading Frames (ORFs) of heterologous genes substitute for ORFs of nonessential genes of a baculovirus

or heterologous ORFs are placed under the control of either viral promoters or nonviral promoters inserted into "neutral" sites of the baculovirus genome. Following infection of cultured insect cells (or larvae) with the recombinant baculovirus, the heterologous gene is expressed. By taking advantage of the several powerful promoters of nonessential genes, the levels and quality of the recombinant protein obtained from insect cells infected with the relevant recombinant baculoviruses are frequently superior to those obtained from other expression systems.

The original description of a recombinant baculovirus for foreign protein expression appeared in a series of articles from Max Summer's laboratory at Texas A&M University in 1983. Their model baculovirus system was the *Autographa californica* nucleopolyhedrosis virus (AcNPV), a member of the nuclear polyhedrosis virus (NPV) subfamily of baculoviruses that have the unique characteristic of producing large proteinaceous occlusion bodies (OBs) during the very late stages of infection. OBs constitute over 25% of the total protein mass within an infected cell (Smith *et al*., 1983a) and serve to protect the mature virions embedded within them from the damaging effects of the natural environment. OBs are mostly composed of a single protein, polyhedrin, whose gene was initially cloned from AcNPV (Smith *et al*., 1983b). Deletions were introduced in the cloned polyhedrin gene in plasmids, and several mutant AcNPVs with an OB negative (OB^-) phenotype were generated by homologous recombination following cotransfection of insect cells with wild-type AcNPV DNA and the plasmid deletions (Smith *et al*., 1983c). Although lacking the ability to synthesize the complete polyhedrin protein, OB^- AcNPVs were still able to infect cultured cells and produce progeny virus. Furthermore, the polyhedrin promoter was shown to remain as active in OB^- AcNPVs and to produce various forms of truncated polyhedrin protein at levels similar to those of the full length polyhedrin protein expressed by the wild-type AcNPV.

Having established that the highly expressed polyhedrin protein was not essential for the survival and propagation of AcNPV, the researchers at Texas A&M constructed various transfer vectors for inserting foreign genes into different positions of the polyhedrin gene region of the AcNPV genome by homologous recombination. Using human beta interferon (IFN-β) as a secreted reporter protein, OB^- recombinant viruses were obtained that expressed either chimeric polyhedrin-interferon proteins or authentic IFN-β under the control of the polyhedrin promoter. The recombinant IFN-β was secreted (with concomitant removal of its signal peptide), glycosylated and biologically active, and was expressed at levels up to 10 μg per ml or 100- to 500-fold higher than what was possible at that time using transformed mouse or bacterial expression systems, respectively (Smith *et al*., 1983b).

The successful expression of IFN-β marked the start of the baculovirus/insect cell protein expression system. Other reports of high-level recombinant protein expression followed soon afterwards, which included the production of a fusion between polyhedrin and *Escherichia coli* β-galactosidase (Pennock *et al*., 1984), human c-Myc (Myamoto *et al*., 1985), and human interleukin-2 (Smith *et al*., 1985).

4.14.2.2. Baculovirus Life Cycle

The baculovirus life cycle has been described in detail elsewhere (O'Reilly *et al*., 1992; Vialard *et al*., 1995; see **Chapter 6.8**).

Members of the *Baculoviridae* family are characterized by a rod-shaped enveloped virion and a circular, double-stranded and covalently closed DNA genome of 60–160 kbp (Mathews, 1982). They infect mainly insects, are not infectious to vertebrates, and are classified under two subfamilies: NPVs and granulosis viruses (GVs), which are members of the subfamily of *Eubaculovirinae* which comprises OB-forming viruses, while under the family of *Nudilibaculovirinae* are classified nonoccluded baculoviruses. Most baculoviruses have a very narrow host range, with the majority of the *Eubaculovirinae* infecting lepidopteran insects. NPVs are also the main constituents of expression vectors, with those species receiving the most attention being AcNPV, first isolated from larvae of the alfalfa looper *A. californica*, and the nuclear polyhedrosis virus of the silkworm *Bombyx mori* (BmNPV).

After an insect dies from an NPV infection, viral OBs, which serve to protect the virions embedded within them from the damaging effects in the natural environment such as UV radiation, are released from the carcass. When these OBs are ingested by an uninfected feeding insect, they are dissolved in the midgut (polyhedrin is solubilized due to the alkaline pH of the gut lumen), and the occluded virions are freed. Following fusion of the virions with midgut epithelial cells, the nucleocapsids migrate to the cell nuclei, where the genome is uncoated and transcription begins. A temporally regulated gene expression cascade ensues, that directs replication and formation of new virions (**Figure 1**).

Two forms of viruses are produced at different phases of the infection cycle: initially nucleocapsids are produced in the nucleus and enveloped upon

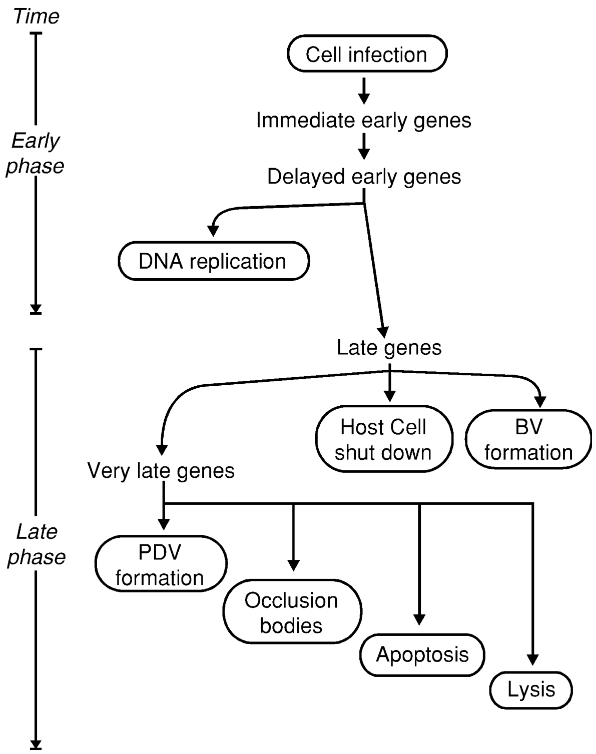

Figure 1 A simplified view of the viral gene expression cascade following baculovirus infection of an insect cell. The cascade is divided into two temporal halves, the first half terminating upon completion of DNA replication of the baculovirus genome, and the second one leading to the production of both budded virions (BVs) and polyhedra-derived virions (PDVs). The infection process ends with the lysis of the host cell.

budding from the cell's plasma membrane. The envelopes of these budded virions (BVs) are also distinguished by the presence of gp64 (also known as gp67), a baculovirus glycoprotein essential for BV entry into the cells by endocytosis (Whitford *et al.*, 1989; Monsma *et al.*, 1996). BVs are responsible for the systemic spread of the infection (secondary infection of neighboring cells or other tissues via the tracheal system of the infected insect). Later in the infection cycle, a second type of virion is generated. These are enclosed, either individually or in association with others, in an envelope of nuclear origin, prior to their incorporation into OBs. This second form, termed polyhedra-derived virions (PDVs), are distinguished from BVs by the association of several viral proteins, including gp41 (Whitford and Faulkner, 1992), p25 (Russell and Rohrmann, 1993), and p74, which is essential for PDV infectivity (Kuzio *et al.*, 1989), with the PDV envelope.

The baculovirus infection of insect cells derived from larval tissues and cultured *in vitro* is similar to that occurring in nature: susceptible cultured cells must be derived from susceptible insect species. OBs, appearing as obvious crystal structures under a simple light microscope, form in the nuclei and are released from lysed cells. Due to the nonalkaline nature of the insect cell culture medium (~pH 6.2), OBs remain insoluble and the PDVs are trapped within them. Thus, the infection is only spread to other cultured cells by BVs. PDVs extracted from OBs can also be used for the primary infection of cultured cells, albeit with significantly lower efficiency than BVs (Volkman and Summers, 1977).

The transcription of the 150 or so baculovirus genes following host cell infection is temporally regulated in four phases (**Figure 1**): immediate early and early genes are transcribed prior to viral DNA replication; late and very late genes are transcribed after replication. Immediate early gene promoters are activated by host factors immediately following uncoating, while delayed early, late, and very late gene promoters require the availability of viral transcription factors, synthesized during the previous phases, for transcriptional activation in the gene expression cascade. Approximately 20 activators of transcription have been identified in AcNPV including IE-1 (Guarino and Summers, 1986), IE-2 (or IE-N; Carson *et al.*, 1988), several late expression factors (LEFs; Lu and Miller, 1995; Rapp *et al.*, 1998) and one very late factor, VLF-1, that is necessary for transcription from the polyhedrin promoter (Yang and Miller, 1999) (for additional details, see **Chapter 6.8**).

4.14.2.3. Early Vectors and Techniques for Generating Recombinant Baculoviruses

Due to the large size of the baculovirus genome, it is difficult to routinely manipulate the baculovirus DNA for ligation of foreign genes directly into its genome. Until recently, the most common approach was to first clone the foreign gene into a plasmid "transfer vector," which is easy to manipulate using regular molecular biology techniques. The purpose of the transfer vector is to target an insertion site in the baculovirus genome for homologous recombination (via double-crossover). Thus, a generic transfer vector contains (1) a promoter, (2) a multiple cloning site for insertion of a heterologous ORF, (3) a poly(A) addition site, and (4) a few kilobase pairs of DNA sequence matching the destination locus in the baculovirus genome flanking elements 1–3. Usually, the destination locus is the polyhedrin region, because the polyhedrin gene promoter is very powerful and the polyhedrin gene itself is nonessential for the virus life cycle *in vitro*. Furthermore, the OB^- phenotype of recombinant viruses facilitates their selection. Most transfer vectors are designed

to simply swap, by homologous recombination, the polyhedrin ORF in the baculovirus genome with a foreign gene, while conserving the polyhedrin promoter and transcription termination [(poly(A) addition site)] regions. Various permutations of this basic approach have also been used (see below).

After the insertion of a foreign gene into the transfer vector is accomplished, the recombinant transfer vector is cotransfected with wild-type baculovirus DNA into insect cells. Within the nucleus, a relatively low frequency genetic exchange, by homologous recombination, occurs between the sequences of the transfer plasmid and the wild-type baculovirus DNA, and a small fraction of recombinant virus is generated. As an alternative to a transfer vector, PCR products generated with primers containing only 50 nucleotides of flanking DNA have also been used successfully, although the frequency of homologous recombination was significantly lower (Gritsun *et al*., 1997). The recombinant viruses can be discriminated visually and isolated from wild-type ones in virus plaque purification assays either based on their OB^{-} phenotype (for the cases of poyhedrin ORF disruption) or by virtue of other visual or molecular phenotypes expressed by them (in the cases where the polyhedrin gene is not disrupted). Another widely used technique for isolating a recombinant virus employs end-point dilution cloning and identity confirmation by PCR, dot-blot hybridization, immunoblotting or activity assays. Once isolated, the recombinant virus is amplified by one or more infection cycles in insect cells. At this point the virus stock is ready for recombinant protein expression. The whole process of preparation of the recombinant transfer vector, cotransfection, purification, amplification, and verification of protein expression usually takes 4 to 6 weeks to complete.

4.14.2.3.1. Polyhedrin promoter As has been already mentioned above, the polyhedrin promoter is by far the most frequently exploited promoter for recombinant protein expression using baculovirus vectors. Initially, transfer vector pAc373 (Smith *et al*., 1985) was used to target the AcNPV polyhedrin gene locus for foreign gene expression. This vector contained a deletion of approximately 182 bp between nucleotides −9 and +175 relative to the polyhedrin ATG translation start site. However, the early studies on the use of this specific and other related transfer vectors revealed that recombinant protein expression was less efficient when the transfer vectors encompassed disruptions in (1) the immediate vicinity of the normal polyhedrin translation start ATG codon, both in the 5′-UTR (Matsuura *et al*., 1987; Possee and Howard, 1987) and the polyhedrin N-terminal region (Luckow and Summers, 1988, 1989); (2) the 15–20 nt upstream of the polyhedrin mRNA transcription initiation site (Possee and Howard, 1987; Rankin *et al*., 1988); and, especially (3) the polyhedrin TAAG transcription initiation site itself (Possee and Howard, 1987; Rankin *et al*., 1988). In addition, it was quickly discovered that the polyhedrin sequences downstream of the poly(A) addition site cannot be deleted extensively due to the presence of an ORF necessary for AcNPV replication (Possee *et al*., 1991). To maximize foreign gene expression from the polyhedrin promoter, improved transfer vectors, such as pAcYM1 (Page, 1989) or pVL941 (Luckow and Summers, 1989), were designed subsequently, which targeted the polyhedrin locus while preserving, through point mutations (ATG to ATC or ATT), the overall context of the region surrounding the normal polyhedrin translation start site.

4.14.2.3.2. *p10* promoter The *p10* gene promoter, another powerful very late phase promoter, was also harnessed as an alternative to the polyhedrin promoter (Vlak *et al*., 1988). P10 is a 10 kDa protein of ambiguous function, probably involved in lysis (van Oers *et al*., 1993) or occlusion body formation (Williams *et al*., 1989), that is not essential for the production of either budded or extracellular virus (Vlak *et al*., 1988), at least *in vitro*. Due to the lack of a selectable phenotype from a recombinant virus targeting the *p10* locus, the β-galactosidase reporter protein was used to identify recombinant viruses. In a report related to comparative aspects of protein production using baculovirus-based vectors, the expression of β-galactosidase and a secreted reporter protein, juvenile hormone esterase (JHE), from recombinant AcNPVs using the *p10* gene promoter were found to be higher and 8 h earlier than that obtained with the polyhedrin promoter (Bonning *et al*., 1994), while work from another group suggested comparable levels of expression (DiFalco *et al*., 1997).

4.14.2.3.3. Basic protein promoter The basic protein is a late gene product associated with the viral DNA within the nucleocapsid. The harnessing of this promoter allows the expression of foreign genes at earlier times than those using the very late phase promoters of the polyhedrin and *p10* genes. As the presence of the basic protein gene was suspected to be essential for viral replication, its deletion was not expected to yield viable recombinant virus. For this reason, its promoter was duplicated and inserted into the polyhedrin gene locus (Hill-Perkins and

Possee, 1990). The promoter duplication was not reported to have an effect on virus stability. Maximal rates of expression of β-galactosidase from recombinant AcNPV using this promoter occurred 3 to 6 h earlier than from the polyhedrin gene promoter but the expression levels were reported to be lower than those obtained using the polyhedrin promoter. Later studies have found, however, that the yields of both β-galactosidase and JHE from recombinant AcNPVs employing the basic protein promoter were higher than those obtained using the polyhedrin promoter (Bonning *et al.*, 1994).

4.14.2.3.4. Constitutive cellular and early viral promoters For the expression of recombinant proteins requiring extensive posttranslational modifications and secretion, the use of late and very late promoters is suboptimal due to the compromising of the normal cellular processes during the late stages of baculovirus infection (Jarvis and Summers, 1989). Moreover, for biopesticide applications involving the expression of insecticidal proteins by recombinant baculoviruses *in vivo* (see **Chapter 6.9**), it is desirable to be in a position to express insect-toxic proteins at an early time in the baculovirus infection cycle.

One alternative to the use of late promoters was the employment of a constitutively active cellular promoter. A recombinant BmNPV was generated that expressed chloramphenicol acetyl-transferase (CAT) reporter protein under control of the *B. mori* cytoplasmic actin promoter (Johnson *et al.*, 1992). The CAT protein could be detected in the infected silkworm cells grown in culture as quickly as 5 h postinfection, compared to 20 h using the polyhedrin promoter, and the overall CAT yield was only threefold lower using the actin promoter relative to that obtained with the polyhedrin promoter. Furthermore, the actin promoter was also shown to function in cultured cells derived from other lepidopteran species such as *Spodoptera frugiperda* and *Choristoneura fumiferana* and could be potentially incorporated into other baculovirus species such as AcNPV.

Similarly, Morris and Miller (1992) generated several recombinant AcNPVs expressing CAT under control of promoter elements obtained from the following genes: *Drosophila melanogaster* hsp70, AcNPV IE-N, AcNPV IE-1, AcNPV IE-0, and AcNPV ETL. While CAT activity could be detected rapidly following infection in most cases, the levels of CAT produced using these promoters were one to two orders of magnitude lower compared to a conventional recombinant AcNPV that employed the polyhedrin promoter to drive foreign CAT expression. For secreted proteins, however, similar or higher overall levels of recombinant protein were obtained from recombinant AcNPVs employing the IE-1 promoter as the driver of foreign gene expression, as compared to a conventional baculovirus expression vector (Jarvis *et al.*, 1996).

4.14.2.3.5. Multiple promoters There are two strategies to accommodate applications, where cells are required to synthesize more than one protein, e.g., for production of antibodies or virus-like particles. One method is to infect cultures with more than one recombinant virus, each expressing a unique protein. This requires a careful determination of the stoichiometric balance of each virus required for achieving consistent ratios of each recombinant protein. The second approach employs multiple transfer vectors for generating a single AcNPV expressing simultaneously several different proteins. Duplication of the polyhedrin gene within one recombinant AcNPV was shown to be feasible (Emery and Bishop, 1987), and this approach was used to produce Bluetongue virus core-like particles (French and Roy, 1990) and monoclonal antibodies (zu Putlitz *et al.*, 1990). Transfer vectors have been also developed for the generation of a single recombinant AcNPV capable of producing up to five different recombinant proteins, by duplication of both the polyhedrin and p10 gene promoters, without causing genetic instability of the viral genome, at least over a course of six passages (Belyaev *et al.*, 1995).

4.14.2.4. Improvements in Baculovirus Expression Vectors

The generation of recombinant baculoviruses using the original protocols is often technically difficult, time consuming, and labor intensive. First, the frequency of a successful homologous recombination event between the transfer vector and wild-type baculovirus DNA is typically in the range of 0.2–1% (O'Reilly *et al.*, 1992), therefore one or more rounds of purification by plaque assay or dilution cloning are necessary for the isolation of a pure recombinant virus. Second, at least one further round of amplification is required in order to generate a suitable viral titer before the virus can be used in a small scale test for expression. In total, this usually takes at least 3–4 weeks and up to 6 weeks (O'Reilly *et al.*, 1992; Luckow *et al.*, 1993). However, over the last decade, several companies have marketed commercially available kits that have capitalized on ingenious molecular biology designs that circumvent some of the bottleneck problems

associated with the traditional methods of preparing recombinant baculoviruses and accelerate their identification and purification.

4.14.2.4.1. Linearized baculovirus DNA Linearization of AcNPV at the destination locus can increase the recovery of recombinant baculoviruses when the former is cotransfected with an appropriate transfer vector (Kitts *et al.*, 1990). AcRP23. LacZ AcNPV DNA (Becton Dickinson/Pharmingen; Possee and Howard, 1987) contains a *lacZ* gene in place of the polyhedrin gene, in addition to a unique *Bsu*361 site that has been introduced downstream of the polyhedrin promoter. Cotransfection of insect cells with *Bsu*361-linearized AcRP23.LacZ and a transfer vector targeting the polyhedrin locus results in approximately 30% of the progeny viruses being recombinant via homologous recombination (Kitts *et al.*, 1990). This reduces significantly the number of progeny viruses that have to be screened in order to achieve purification of recombinant ones. Furthermore, the isolation of recombinants in plaque assays or limiting dilution assays is facilitated by the fact that the recombinants do not produce LacZ and appear colorless, as opposed to the parental blue ones, in the presence of X-gal. Linearized AcUW1. LacZ DNA (Becton Dickinson/Pharmingen; Weyer *et al.*, 1990) is a modified AcNPV DNA similar to AcRP23.LacZ but designed to be used with transfer vectors targeting the *p10* gene promoter.

BaculoGold™ DNA (Becton Dickinson/Pharmingen) and BacPAK™ (Clontech) are modified AcNPV DNAs with three *Bsu*36I sites inserted in the vicinity of the polyhedrin locus (Kitts and Possee, 1993). Digestion of the DNAs with *Bsu*36I yields linear DNAs encompassing a lethal deletion in the essential ORF 1629 (Possee and Howard, 1987) that maps downstream of the polyhedrin locus, and this precludes the generation of a viable virus upon self-ligation of the restricted parental viral genome. When provided with a transfer vector spanning the deleted region, homologous recombination in the transfected insect cells rescues the lethal deletion. Over 99% of viruses produced by the transfected cells are recombinants and only one round of purification is necessary. These DNAs also contain a *lacZ* gene at the polyhedrin locus, which is substituted for by the gene of interest in a successful recombination event. Thus, the isolation of recombinant baculoviruses by plaque or limiting dilution assays is facilitated by the lack of expression of LacZ and the presence of colorless infected cells upon addition of X-gal. BaculoGold™ Bright (Becton Dickinson/Pharmingen) recombinant baculoviruses express the green fluorescence protein (GFP), that can be visualized 24 h postinfection (p.i.), under the control of the *p10* gene promoter. This can facilitate the purification of recombinant virus by fluorescence activated cell sorting (FACS) sorting of single GPF positive cells. The titration process is also simplified by FACS analysis or by a serial dilution and visualization using fluorescent microscopy.

BacVector® (Novagen) and Bac-N-Blue™ (Invitrogen) are modified linearized AcNPV DNAs similar to BaculoGold™ and BacPAK™. They also contain a lethal deletion in ORF1629 that is rescued by a transfer vector. The relevant transfer vectors target the polyhedrin locus and contain reporter genes encoding either β-glucuronidase (pBac, Novagen) or β-galactosidase (pBlueBac, Invitrogen) under the control of the AcNPV ETL promoter. This allows for visual identification of a successful homologous recombination event by the scoring of blue (recombinant) plaques in a background of colorless ones following the addition of X-gluc or X-gal, respectively. Finally, BacVector-3000 is a modified linearized AcNPV DNA (Novagen) containing deletions of several nonessential genes that, apparently, compete with target protein production, in addition to deletions of the genes encoding two baculovirus degrading enzymes, cathepsin and chitinase, which are claimed to destabilize recombinant proteins.

4.14.2.4.2. Shuttle vectors Certainly one of the most ingenious and fastest methods to generate recombinant AcNPV is the Bac-to-Bac® expression system (Luckow *et al.*, 1993), licensed to Invitrogen (formerly Life Technologies) by Monsanto. In this system, the recombination event between the AcNPV and transfer vector occurs in *E. coli* DH10B by site-specific transposase-mediated insertion, as opposed to homologous recombination in insect cells. The DH10Bac™ strain harbors a modified AcNPV genome, known as bacmid, that is essentially a large (136 kbp) shuttle plasmid containing, in addition to the baculovirus genome sequences, a kanamycin resistance marker, a low copy number mini-F replicon for retention and replication in *E. coli*, and the target site *att*Tn7 for the Tn7 bacterial transposon in the polyhedrin locus. A helper plasmid providing Tn7 transposase is also maintained in the DH10Bac™ strain by tetracyclcine resistance. When DH10Bac™ cells are transformed with a third plasmid containing the gene of interest flanked by Tn7 elements, transposition of the gene of interest occurs to the Tn7 target site in the polyhedrin locus of the bacmid. The successful transposition disrupts the expression of a

LacZ reporter gene in the bacmid, so that generation of a recombinant bacmid results in white *E. coli* colonies in blue background colonies arising from unaltered parent cells. The recombinant bacmid DNA is isolated from minipreps of white colonies and then used to transfect insect cells and generate viral stocks for small-scale recombinant protein expression. The whole process is reported to take 7–10 days (Luckow *et al.*, 1993).

Patel *et al.* (1992) also described a rapid method for generating recombinant baculoviruses by homologous recombination between a modified AcNPV genome propagated in yeast and a baculovirus transfer vector containing yeast sequences. With this yeast-baculovirus shuttle system, it is reported that recombinant viral stocks can be obtained within 10–12 days. This system is not available from a commercial supplier.

4.14.2.4.3. Direct cloning Several publications have also appeared describing direct cloning of the gene of interest into polyhedrin locus of the AcNPV genome (Ernst *et al.*, 1994; Lu and Miller, 1996). Modified AcNPV's were generated that could be linearized with restriction enzymes in the polyhedrin locus. Ligation with the foreign gene fragment *in vitro* and transfection of the ligation mix into insect cells resulted in the percentage of recombinant viruses approaching 100%. Invitrogen Corporation has recently developed Baculodirect™, a direct cloning strategy for generating recombinant AcNPV using the well-characterized lambda-phage site-specific recombination system (Gateway™) as opposed to a homologous recombination. In addition, the recombination event transferring the desired gene to the polyhedrin locus also includes the HSV thymidine kinase (TK) selection marker that is driven by the IE-1 promoter. Once the *in vitro* recombinase reaction is complete, the reaction contents are transfected into insect cells and selective pressure of ganciclovir is applied so that only those viruses harboring the TK resistance marker can replicate. Within 7 days, purified viral stocks are available for expression studies.

4.14.2.5. Cell Lines Used as Hosts for Baculovirus Expression Vectors

With the popularity of the BES and the fact that the vast majority of baculovirus expression vectors are based on AcNPV, it is not surprising that recent developments in insect cell culture have focused on cell lines derived from species that can support both the replication of AcNPV and the high level expression of foreign proteins under control of the AcNPV polyhedrin, p10 and basic protein gene promoters. AcNPV has a relatively broad host range among lepidopteran species and cell lines established from them, including the fall armyworm *S. frugiperda*, the cabbage looper *Trichoplusia ni*, the tobacco budworm *Heliothis virescens* and the gypsy moth *Lymantria dispar*. However, those cell lines that are the most widely used to date as hosts for protein expression include IPLB-Sf21AE (Vaughn *et al.*, 1977) established from *S. frugiperda* pupal ovaries, its subclone Sf9 (Summers and Smith, 1987) and BTI-Tn-5B1-4 or High Five™ cells established from *T. ni* embryos (Granados *et al.*, 1994). These cell lines are well characterized and have a history of good growth and recombinant protein expression in serum-free culture medium and in large-scale suspension cultures. In contrast to AcNPV, BmNPV has a narrow host range; Bm5 (Grace, 1967) and BMN-4 cells (Maeda, 1989) established from *B. mori* ovarian tissue cells are used as host cells for BmNPV infections. Although both Bm5 and BMN-4 lines can be propagated in serum-free media, Bm5 cells have superior growth characteristics in suspension culture (Keith *et al.*, 1999) and have been reported to produce recombinant protein in bioreactors (Zhang *et al.*, 1993).

4.14.2.6. Classes of Recombinant Proteins Expressed by Baculovirus Infected Insect Cells

Insect cells are capable of most types of posttranslational modifications that occur in mammalian cells. They include signal peptide cleavage, N- and O-linked glycosylation (although they may not be capable of a significant level of complex glycosylation), phosphorylation, acylation, palmitylation, myristoylation, prenylation, amidation, and carboxymethylation (see Luckow, 1991 for an extensive compilation to that date). Heterologous proteins are also correctly targeted to their subcellular destination including plasma membranes, cytosol, lysosomes, mitochondria, nuclei, or nucleoli. Hence, different classes of recombinant proteins from a variety of organisms have been expressed successfully using the baculovirus expression system. These include cytoplasmic proteins, structural proteins, lysozomal enzymes, membrane receptors, ion exchangers, transport proteins, and nuclear factors (Table 1).

Although it is unwise to make gross generalizations, some classes of proteins are certainly expressed at much higher levels than others, and each individual protein within a class will often have its own unique troublesome characteristics that a researcher will have to deal with: some proteins may form insoluble aggregates, others are more vulnerable to proteolysis (especially following

lysis when degradative enzymes are released), secretion may be inefficient, expression levels may be low and those proteins requiring a physiologically intact cell membrane may have to be harvested prematurely.

4.14.2.6.1. Intracellular proteins Clearly the most successful application of the baculovirus expression system is for expression of intracellular recombinant proteins. Expression levels over 100–200 mg l^{-1} are not uncommon (**Table 1**) and proteins may be released by the cells into the culture medium following virus-induced lysis to simplify purification. Insoluble aggregates of recombinant intracellular protein within the cell have occasionally been reported (Alnemri and Litwack, 1993; Rankl *et al*., 1994; Baldock *et al*., 2000). In rare cases, the fusion of an insect-derived signal peptide to the N-terminus of a normally intracellular targeted protein has been successful for secreting the intracellular protein (Mroczkowski *et al*., 1994; Laukkanen *et al*., 1996).

4.14.2.6.2. Secreted proteins Secreted proteins are usually expressed at much lower levels compared to intracellular proteins, usually in the order of 10 mg l^{-1} (**Table 1**). This is thought to be due to a breakdown in the secretory pathway in the late stages of infection, when foreign gene expression from late and very late promoters is maximal (Jarvis and Summers, 1989). Three approaches have been tried to improve the efficiency of secretion. In the first approach, the substitution of the native signal peptide of a heterologous secreted protein with an insect-specific signal peptide, such as those of the honeybee mellitin (Tessier *et al*., 1991; Jarvis *et al*., 1993), *Drosophila* cecropin B (Jarvis *et al*., 1993), AcNPV 64K (Jarvis *et al*., 1993), AcNPV gp67 (Golden *et al*., 1998; Murphy *et al*., 1993), AcNPV chitinase (Chen *et al*., 2000), and AcNPV egt (Murphy *et al*., 1993), was expected to make secretion more efficient. In some cases expression was improved dramatically using insect-specific signal peptides (Murphy *et al*., 1993; Chen *et al*., 2000), while in others the modifications proved ineffective (Jarvis *et al*., 1993; Golden *et al*., 1998). In the second approach, the use of an earlier promoter (but weaker than late and very late promoters) such as IE-1 to drive the expression of a heterologous secreted protein, before the secretory pathway was compromized, resulted in only a slight improvement in the expression level (Jarvis *et al*., 1996). The third approach was to coexpress a molecular chaperone protein such as immunoglobulin heavy chain binding protein (BiP), although no improvement in secretion of immunoglobulin was observed (Hsu *et al*., 1994). If glycosylation is not important for a particular secreted protein, one strategy to improve expression is to remove the signal sequence altogether. This will prevent its entry into the secretory pathway and disguise the protein as an intracellular protein. Unpublished results from Dr Bruce Hammock's laboratory (personal communication) have shown an improvement in the expression of active *H. virescens* JHE from 4 to 75 mg l^{-1} using this strategy (**Figure 2**).

4.14.2.6.3. Membrane proteins The reputation of the baculovirus expression system for lower expression levels of proteins destined for the secretory pathway compared to other proteins (Jarvis and Guarino, 1995) also applies to membrane proteins. This said, expression levels of membrane proteins are often higher than those achieved with other expression systems; the expression of membrane proteins in bacteria, for example, is largely unsuccessful. Certainly many laboratories have used the BES to express and purify a variety of membrane proteins. Some examples include ion exchangers (Li *et al*., 1992; Dale *et al*., 1996; Egger *et al*., 1999), G protein-coupled receptors (GPCRs) (Strosberg and Guillaume, 2000; reviewed by Bouvier *et al*., 1998; Carpentier *et al*., 2001), transport proteins (Smith *et al*., 1992; Tate, 1998; Gao *et al*., 1999; Miyasaka *et al*., 2001), adhesion molecules (Stoltenberg *et al*., 1993; Nagarajan and Selvaraj, 1999; Phan *et al*., 2001), and other membrane proteins (Xiao *et al*., 2000; Soares *et al*., 2001; Sun *et al*., 2002). Purified levels obtained are generally in the range of 0.1–10 mg l^{-1} (Chinni *et al*., 1998; Carpentier *et al*., 2001; Miras *et al*., 2001; Soares *et al*., 2001). There are numerous reports of either inactive, immature, misfolded membrane proteins or incompletely glycosylated forms of baculovirus-expressed membrane proteins (Pajot-Augy *et al*., 1995; Vasudevan *et al*., 1995; Loisel *et al*., 1997; Massotte *et al*., 1997; Tate, 1999; Sun *et al*., 2002). Improvements in the yields of active membrane proteins have been obtained by the coexpression of molecular chaperones including calreticulin, BiP, cannexin, and nina A (Tate, 1999; Miyasaka *et al*., 2001; Lenhard and Reilander, 1997).

For those studying membrane protein signaling events following ligand binding, there can be some difficulties using the BES. Obviously, there is the fact that an inherent property of the baculovirus is that it will ultimately kill the host cell. Thus, only a short window of opportunity exists for the study of receptor signaling events in live cells, between the moment of expression from a late- or very late-phase promoter and cell death. Some investigators have

Table 1 Expression levels of some secreted and intracellular proteins expressed using the baculovirus expression system. The expression levels reported are in mg per liter of *unprocessed* cell culture

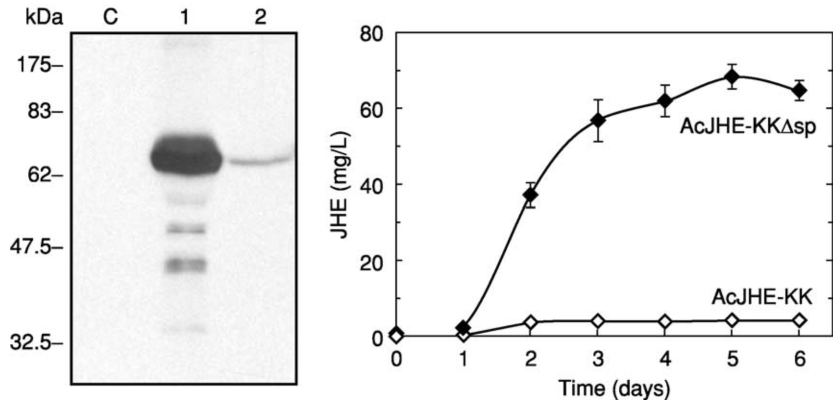

Figure 2 One technique to improve the expression level of secreted proteins from baculovirus infected insect cells involves the removal of the signal peptide encoded by the gene and the creation of an artificial ATG at the start of the mature polypeptide coding region in the expression vector. This modification prevents the nascent polypeptide from entering the secretory pathway. In this example, the yield of biologically active juvenile hormone esterase (JHE) present in the culture supernatant of recombinant AcNPV-infected Sf21 cells is enhanced approximately 20-fold when the JHE signal peptide is removed (AcJHE-KKΔsp) compared to the full length gene AcJHE-KK (Bonning *et al.*, 1997). Left panel: Western blot analysis of 5 μl culture media to confirm the relative JHE expression levels in static cultures. Lane C, control culture medium; lane 1, day 6 cultutre medium form AcJHE-KKΔsp infected Sf21 cells; lane 2, day 6 culture medium from AcJHE-KK infected Sf21 cells. Right panel: Batch production of JHE by AcJHE-KK or AcJHE-KKΔsp-infected Sf21 cells in serum-containing medium in 6-well plates over a 6-day period. Note that JHE produced by AcJHE-KKΔsp was not directed through the secretory pathway.

used membrane preparations from infected cells rather than the cells themselves to carry out their studies (Clawges *et al.*, 1997). In addition, coupling of heterologous receptors with endogenous insect cell host proteins, such as G proteins, has generally produced low responses upon ligand binding (see below). This problem has been circumvented by coexpressing a GPCR with specific G protein subunits in order to assess agonist binding (Butkerait *et al.*, 1995; Barr *et al.*, 1997; Bouvier *et al.*, 1998).

4.14.2.6.4. Compartmentalized proteins The BES has also been employed to synthesize and correctly process proteins targeted to subcellular compartments. A variety of mitochondrial proteins have been expressed using the BES, both membrane associated (Yet *et al.*, 1995; Bader *et al.*, 1998; Huang *et al.*, 2000) and located within the mitochondrial matrix (Wang and Kaguni, 1999; Holcomb *et al.*, 2000), although the latter reported incomplete processing and inefficient targeting. Lysosomal enzymes have also been successfully expressed (Tschantz *et al.*, 1999; Bromme and McGrath, 1996; Steed *et al.*, 1998), as has a nucleolar protein (Ren *et al.*, 1996) and a nuclear membrane protein (Bailer *et al.*, 1995).

4.14.2.7. Other Applications of the Baculovirus Expression System

4.14.2.7.1. Virus-like particles The baculovirus expression system has proven to be very effective for the production of heterologous virus-like and core-like particles (VLPs and CLPs) destined for use in immunization or structural studies. Some examples include the poliovirus VLP (Urakawa *et al.*, 1989), bluetongue virus CLP (French and Roy, 1990), Norwalk virus (Jiang *et al.*, 1992), the papillomavirus (Cann *et al.*, 1995), and herpes simplex virus (Newcomb *et al.*, 1999). VLPs and CLPs can be architecturally complex and comprising several structural proteins in different molar

human immunodeficiency virus glycoprotein 120; PSA, prostrate specific antigen; JHE, *Heliothis virescens* juvenile hormone esterase; IL-5, interleukin-5; OSF-2, murine osteoblast specific factor 2; HCII, heparin cofactor II; GalNAc-transferase, bovine UDP-GalNAc polypeptide *N*-acetyl galactosaminyl transferase; LIF, leukemia inhibitory factor; Apo A1, apolipoprotein A-I; FAK, focal adhesion kinase; GHBP, growth hormone binding protein; MMP9 matrix metalloproteinase-9; α_1m–α_1, microglobulin; CatK, cathepsin K; STC, stanniocalcin; GL, gastric lipase; OPG-Fc, osteoprotegerin-immunoglobulin Fc fusion; proPAP, *Manduca sexta* prophenoloxidase-activating proteinase precursor; proPAP-2, *M. sexta* prophenoloxidase-activating proteinase-2 precursor; IL-3, interleukin-3; CAT, bacterial chloramphenicol acetyl-transferase; VP6, rotavirus VP6; β-gal, beta galactosidase; VP4, rotavirus outer capsid protein; ACL, ATP citrate lyase; NFκB1/RelA, subunits of the NF-κB transcriptional activator of immunoglobulin κ light chain; M/NEI, monocyte/neutrophil elastase inhibitor; Syk, Syk protein; EBNAI, Epstein-Barr virus nuclear antigen 1; PARP, poly(ADP-ribose) polymerase; KSHV Pol, Kaposi's sarcoma-associated herpesvirus DNA polymerase).

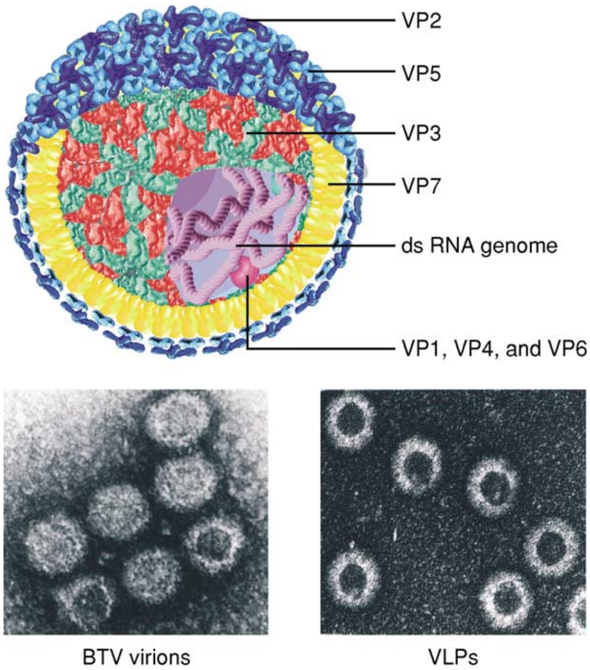

Figure 3 A comparison of electron micrographs of native blue-tongue virus (BTV) virions with recombinant BTV virus-like particles (VLPs) produced and self-assembled in baculovirus-infected insect cells. For optimal synthesis of the BTV VLPs, a quadruple gene expression vector was used to co-express BTV VP2, VP3, VP5, and VP7 proteins (Roy *et al.*, 1997). At the top of the figure, a model of the BTV virion is shown. Images kindly supplied by Dr Polly Roy (London School of Hygiene and Tropical Medicine, UK).

proportions. It was observed that the coexpression of the various VLP structural proteins in baculovirus-infected insect cells results in the self-assembly of the VLP (Urakawa *et al.*, 1989). Initially, the various structural proteins were produced by coinfection with individual recombinant baculoviruses. However, variation in the distribution of individual recombinant baculoviruses to each cell would result in differences in the quality of the VLP. Coexpression of proteins of the VLP or CLP using a single baculovirus with multiple promoters circumvents this problem (**Figure 3**; French and Roy, 1990; Belyaev *et al.*, 1995). The ratio of each protein expressed can be controlled through the use of baculovirus promoters of different strength (Roy *et al.*, 1997).

4.14.2.7.2. Surface display and antibody production The baculovirus virion has been developed as an eukaryotic alternative to the bacteriophage for the surface display of foreign proteins from an expression library and the selection of specific binding proteins (review: Grabherr *et al.*, 2001). By duplicating the essential major envelope glycoprotein gene encoding gp64 in the baculovirus genome, it was shown that foreign proteins (X) could be presented on the mature N-terminus of the duplicated X-gp64 (fusion) protein, in the envelope of BVs (Boublik *et al.*, 1995). A demonstration of the feasibility of using baculovirus display for the screening of a library has been described (Ernst *et al.*, 1998). Immunization of mice with purified virions displaying X-gp64 fusion proteins has also been useful for obtaining polyclonal and monoclonal antibodies against the antigen X (Lindley *et al.*, 2000). This procedure eliminates one bottleneck in the conventional antibody production process of having to generate purified protein X for immunization. Due to an immunostimulatory effect often associated with viral immunogens (Minev *et al.*, 1999), this method may be more effective than the conventional process for raising antibodies against certain antigens (Lindley *et al.*, 2000).

4.14.2.7.3. Expression of recombinant proteins in insect larvae Insect larvae have occasionally been employed, instead of cultured insect cells, as hosts for recombinant baculoviruses for the expression of recombinant proteins (Maeda *et al.*, 1985). Production in larvae can be inexpensive, high yielding, and easily scalable compared to cell culture. Yields around 1 mg per silkworm larva infected with recombinant BmNPV have been obtained for human interleukin-3 (Miyajima *et al.*, 1987), hepatitis B surface antigen (Higashihashi *et al.*, 1991), human CD66 antigens (Yamanaka *et al.*, 1996), grass carp growth hormone (Ho *et al.*, 1998), hepatitis E virus capsid protein (Sehgal *et al.*, 2003), and human fibroblast growth factor (Wu *et al.*, 2001). A bovine cardiac sodium–calcium exchanger has also been successfully expressed in *T. ni* larvae (Hale *et al.*, 1999). However, the recovery of the expressed protein may be more problematic from larvae than from tissue culture because of increased proteolysis in the insect hemolymph and contamination of preparations by abundant hemolymph proteins.

4.14.2.7.4. Baculovirus transducing and transforming vectors Because of their ability to enter efficiently host and nonhost insect cells alike, baculovirus vectors can be designed with the goal of overexpressing regulatory factors and studying their role during development. Because baculoviruses are normally lethal to the host tissues, expression studies are by necessity limited to a brief period of experimentation extended between the initial infection and the activation of the host cell lysis process (Iatrou and Meidinger, 1989). For lepidopteran insect systems, this problem can be

circumvented by the construction and use of mutant viruses that are unable to proceed through the late phases of the infection cycle. By contrast, infection of tissues of nonhost insects that are refractory to productive infection can result in more extended periods of expression and experimental observation (Oppenheimer *et al*., 1999).

Two approaches have been utilized for the generation of transgenic lepidopteran insects using baculoviruses. One exploits the fact that AcNPV can infect nonhost lepidopteran insect larvae without killing the insect (Mori *et al*., 1995; Oppenheimer *et al*., 1999). Due to this property, the AcNPV can be used as a vehicle to efficiently deliver a transgene to germline cells, which is then targeted to chromosome sites for homologous recombination and generation of transgenic progeny (Yamao *et al*., 1999). A second approach uses a recombinant baculovirus with a deleted *lef-8* gene (Iatrou *et al*., 2000). The *lef-8* gene encodes a subunit of the viral RNA polymerase (Passarelli *et al*., 1994) that is necessary for mRNA transcription from the promoters of late and very late-phase baculovirus genes. Loss-of-function mutations in this gene prevent the progression from the replication phase to the virulent phase of the baculovirus infection cycle (Shikata *et al*., 1998). Accordingly, deletions of the *lef-8* gene convert the baculovirus to a harmless, self-replicating extra-chromosomal entity (baculovirus artificial chromosome – BVAC), while host cells infected by it behave as normal ones (P.J. Farrell and K. Iatrou, unpublished results). Passage of the *lef-8* deficient baculovirus through a rescuing cell line that constitutively expresses the Lef-8 protein enables the production of BVAC inoculum that maintains full infectivity for and replicating capacity in the host cells (**Figure 4**).

The BVACs could potentially be used for prolonged protein expression by taking advantage of the high initial infection efficiency of cells by the baculovirus, the replication of the BVACs in them, and the subsequent mitotic transmission of the transgene-containing BVAC to the daughter cells. Furthermore, the prevention of both virus-induced damage to the secretory pathway and lysis would make BVACs more suitable for the expression of secreted and membrane proteins under the control of early viral or cellular promoters than conventional baculovirus expression vectors. Efforts are also being made to generate transgenic silkworms through the infection of germline cells with BVACs derived from BmNPV.

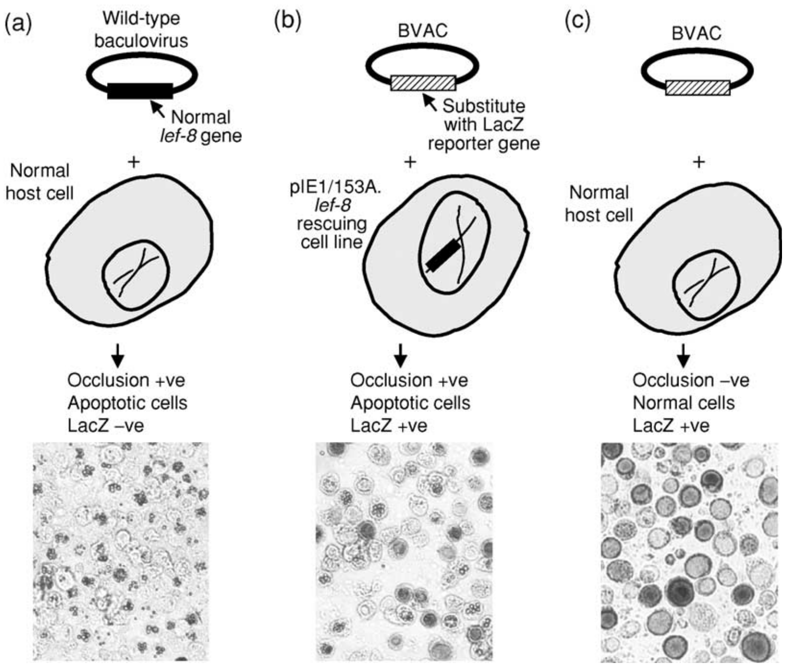

Figure 4 The potential for a nonlytic baculovirus is demonstrated. (a) Infection of normal insect cells by a wild-type baculovirus. The infected cells produce OBs (small, refractive objects) and eventually lyse. (b) A baculovirus artificial chromosome (BVAC) is created when the *lef-8* gene is eliminated and replaced with a reporter gene expression β-galactosidase (dark cells). When the *lef-8* gene product is supplied by a transformed cell line, the BVAC can complete the infection cycle that includes the formation of budded virions and occlusion bodies and cell lysis, in addition to the production of β-galactosidase. (c) The absence of the *lef-8* gene product, in normal permissive cells infected by a BVAC, prevents completion of the baculovirus infection cycle. OBs are absent, the cells appear and replicate normally, and also express β-galactosidase.

4.14.2.7.4. Transduction of mammalian cells Baculovirus virions were demonstrated to have the ability to enter certain cell lines derived from vertebrate species without evidence of viral gene expression (Volkman and Goldsmith, 1983; Carbonell and Miller, 1987). By incorporating mammalian expression cassettes into recombinant AcNPVs, several reports have appeared demonstrating that baculoviruses can serve as an efficient mode of gene transfer into a variety of primary and transformed mammalian cell lines, including those difficult to transfect using traditional methods, and express reporter proteins under the control of mammalian promoters (Hoffmann *et al*., 1995; Boyce and Bucher, 1996; Shoji *et al*., 1997; Yap *et al*., 1997; Condreay *et al*., 1999). Chromosomal integration and stable gene expression have also been demonstrated to be feasible by inclusion of a selectable marker (Condreay *et al*., 1999; Merrihew *et al*., 2001) or by integration signals from adeno-associated virus (AAV) into the baculovirus genome (Palombo *et al*., 1998). The advantages of using the baculovirus in this application include the high transfection efficiency (often greater than 90%; Condreay *et al*., 1999), low toxicity of the baculovirus to mammalian cells, and capacity of the baculovirus to carry large inserts. Recently, hybrids of the baculovirus and AAV were used to coinfect mammalian cells and produce high titer recombinant AAV for gene therapy applications (Sollerbrant *et al*., 2001).

4.14.3. Insect Cells as Hosts for Plasmid-Based Expression of Recombinant Proteins

4.14.3.1. Introduction

Several baculovirus-free, plasmid-based approaches to recombinant protein expression in insect cells have been developed. In this technique, a plasmid expression cassette harboring a gene of interest is introduced into the host insect cell line using a variety of transfection techniques. The recombinant protein will be transiently expressed for a few days after transfection whereupon the cells or their media containing the recombinant protein can be harvested. Stable cell lines expressing the recombinant protein of interest, either continuously or by induction, can be generated by applying an antibiotic resistance-selection scheme over a period of several weeks. The antibiotic resistance gene can either be present on the same expression cassette as the gene of interest or supplied by cotransfection with a separate plasmid. Antibiotic selection schemes conferring resistance to G418 (Jarvis *et al*., 1990), hygromycin B (Johansen *et al*., 1989), methotrexate (Shotkoski and Fallon, 1993), puromycin (McLachlin and Miller, 1997), and zeocin (Pfeifer *et al*., 1997) have all been used extensively with insect cell lines.

The production of recombinant proteins in transfected or stably transformed insect cells provides considerable advantages over both the baculovirus expression system and transformed mammalian cells for the case of applications involving secreted and membrane-anchored proteins: insect cell lines are safe to humans, introns are spliced correctly and efficiently from expressed genomic DNAs and lysis does not occur, therefore allowing continuous, as opposed to batch-type, expression of the proteins and limiting proteolysis and facilitating purification of the secreted proteins. Furthermore, insect cells can perform most essential posttranslational modifications as efficiently as mammalian ones, and membrane proteins can be expressed in a stable physiological environment. Finally, most insect cell lines can grow in serum-free media to high densities, and many insect cell lines, particularly of lepidopteran origin, are already well characterized in large-scale suspension culture because of their role as hosts in the baculovirus expression system.

Two major categories of plasmid-based expression systems have been developed utilizing promoters and cell lines derived from two different insect orders, Diptera and Lepidoptera. These are presented in more detail below.

4.14.3.2. Expression Systems Based on Dipteran Cell Lines

Dipteran expression vectors mostly utilize the strong constitutive actin 5C promoter of *D. melanogaster* (Angelichio *et al*., 1991) or the inducible metallothionein promoter of *Drosophila* (Johansen *et al*., 1989; Kovach *et al*., 1992; Millar *et al*., 1995; Hegedus *et al*., 1998; Zhang *et al*., 2001) to drive foreign protein expression, in conjunction to a hygromycin B antibiotic selection scheme to generate a polyclonal population of Schneider 2 cell lines (S2 cells; Schneider, 1972), which takes approximately 3 weeks to accomplish (Johansen *et al*., 1989). The latter system has been developed by SmithKline-Beecham Pharmaceuticals and made commercially available through Invitrogen Corporation as the Drosophila Expression System (DES®). *Drosophila* S2 cells can grow in serum-free medium in batch suspension culture to cell densities up to 15×10^6 cells ml^{-1}, although S2 cells are substantially smaller than most lepidopteran cell lines including Sf21, High Five™, and Bm5

Table 2 Expression levels of some secreted proteins from stably transformed insect cells

cells. Enzymes, membrane receptors, ion channels, viral antigens, and monoclonal antibodies have been successfully produced using these systems (see Table 2).

4.14.3.3. Expression Systems Based on Lepidopteran Cell Lines

Lepidopteran expression vectors utilize a variety of promoters derived from baculoviruses and lepidopteran cells, including the AcNPV *ie-1* promoter, the OpNPV *ie-2* promoter, and the *B. mori actin* gene promoter; these promoters function mainly in lepidopteran cell lines such as Sf21, Sf9, High Five™, or Bm5 cells.

4.14.3.3.1. Constitutive expression

4.14.3.3.1.1. Baculovirus immediate early promoters A lepidopteran insect cell-based expression system was initially developed by Dr Don Jarvis at Texas A&M University (Jarvis *et al.*, 1990). To generate stably transformed cell lines, Sf9 cells were cotransfected with a neomycin resistance plasmid, an expression vector employing the AcNPV immediate early gene promoter (*ie-1*) and a region containing mRNA polyadenylation signals (Guarino and Summers, 1987), followed by selection and isolation of G418 resistant clones over a period of 4 weeks following transfection. From the transformed insect cell clones, the expression levels of β-galactosidase (an intracellular protein) were approximately 100-fold lower than those obtained from a baculovirus expression vector employing the polyhedrin promoter, while the level of t-PA (a secreted protein) obtained was only two-fold lower. Despite the low values, these experiments demonstrated the potential of using stable lepidopteran cell lines for producing those recombinant proteins directed through the secretory pathway as an alternative to a baculovirus. The *ie-1* gene promoter was also shown to function in dipteran cell lines (Vanden Broeck *et al.*, 1995). Improvements in the expression vector were made by incorporating the AcNPV homologous repeat 5 (HR5) transcriptional enhancer element (Guarino *et al.*, 1986) upstream of the *ie-1* promoter (Jarvis *et al.*, 1996). HR5 was shown to act in *cis* to significantly stimulate the expression of a reporter protein from early baculovirus promoters such as *ie-1* and *p35* in transient expression assays (Rodems and Friesen, 1993; Pullen and Friesen, 1995). A series of vectors utilizing the HR5-enhanced AcNPV *ie-1* promoter are available from Novagen for stable or transient protein expression. A similar set of expression vectors has been developed based on the *Orgyia pseudotsugata* multicapsid nuclear polyhedrosis virus (OpMNPV) *ie-2* promoter (Theilmann and Stewart, 1992; Pfeifer *et al.*, 1997; Hegedus *et al.*, 1998), which can function in both lepidopteran and dipteran insect cell lines. These vectors are available from Invitrogen as the Insect Select™ vector set.

4.14.3.3.1.2.* Bombyx mori *cytoplasmic actin promoter A powerful lepidopteran expression cassette, pIE1/153A, was recently developed in the laboratory of Dr Kostas Iatrou at the University of Calgary. The cassette utilizes the silk moth (*B. mori*) cytoplasmic actin gene promoter (Mounier and Prudhomme, 1986; Johnson *et al.*, 1992), one of the stronger constitutive cellular promoters that is also active in a variety of transfected lepidopteran cell lines. Transcription from this cellular promoter was surprisingly found to be stimulated by the immediate early gene product (*ie-1*) of BmNPV, IE-1, a transcription factor capable of stimulating the *in vitro* rate of transcription from the actin promoter in *trans* by up to 100-fold (Lu *et al.*, 1996). Stimulation of the actin promoter by up to two orders of magnitude was also obtained by linking in *cis* the homologous repeat 3 (HR3) region of BmNPV in various orientations relative to the actin promoter (Lu *et al.*, 1997). Linkage of the *ie-1* gene and the HR3 enhancer element with the actin gene promoter in the pIE1/153A expression cassette resulted in a stimulation of foreign gene expression directed by the actin promoter by approximately 5000-fold in transient expression assays for two reporter proteins (Lu *et al.*, 1997). Stable cell lines have been generated by cotransfecting the cells with the expression cassette and a second plasmid conferring resistance to hygromycin B, puromycin, or G418. Reported expression levels of secreted proteins from stable cell lines transformed with this system have exceeded, by far, those obtained by the baculovirus expression system (Farrell *et al.*, 1998; Farrell *et al.*, 1999). Furthermore the expression plasmid functions in a wide variety of lepidopteran cell lines including those derived from *B. mori*, *T. ni*, *Plodia interpuntella*, *L. dispar*, *Mamestra brassicae*, *C. fumiferana*, and *S. frugiperda* (Keith *et al.*, 1999). The expression cassette is also suited to scaled-up transient expression protocols that can yield tens of milligrams of recombinant protein per liter in 5 days posttransfection (Farrel and Iatrou, 2004) (**Figure 5**), thus avoiding the time consuming and labour intensive process of stable antibiotic selection and the cloning of high expressors. Derivatives of the pIE1/153A expression cassette are available from Dr Iatrou.

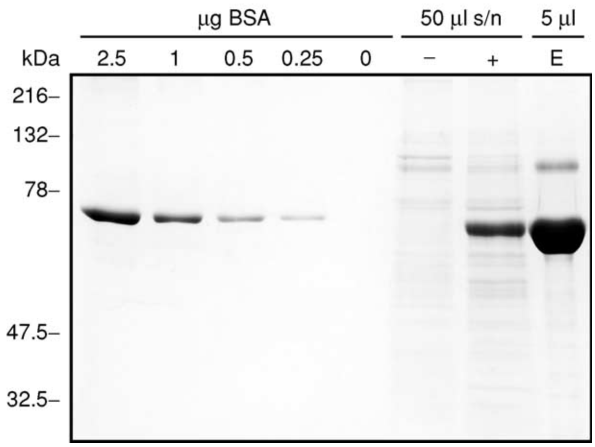

Figure 5 Transient expression and affinity purification of histidine-tagged human secreted alkaline phosphatase (SEAP; kindly provided by Eric Carpentier and Amine Kamen, Biotechnology Research Institute, Montreal, Canada) from a lipofectin-mediated transfection of High Five^{TM} cells in suspension culture using the pIE1/153A expression cassette. By comparison to a series of bovine serum albumin mass standards on the Coomassie blue-stained gel, approximately 50 µg ml^{-1} of SEAP was present in the culture supernatant 5 days after transfection and production in protein-free medium ESF-921 (lane marked "+" compared to control marked "−"). Two milligram of SEAP was recovered from one elution fraction (E) following Ni-ion affinity purification from 50 ml of culture supernatant.

4.14.3.4. Insect Cell-Based Expression Using Inducible Promoter Systems

In contrast to constitutive promoters, the use of inducible promoters has the advantage that it allows the production of proteins that are toxic or growth-inhibitory to the cells. In such cases, cells are first grown in batch mode (rather than continuously) to high densities. When sufficiently high densities are reached, the inducer is added to the cell culture to induce high-level protein expression. Of importance to the choice of an inducible expression system is the induction ratio of gene expression. In the absence of inducer, promoter activity should be minimal as to prevent accumulation of toxic proteins during the growth phase of the cells. Addition of the inducer should, subsequently, result in the accumulation of high amounts of protein.

4.14.3.4.1. Heat shock promoter The *Drosophila hsp70* promoter (Thummel and Pirrotta, 1992) has been widely used to achieve inducible gene expression in transgenic flies. The promoter is heat-inducible and functions during all stages of development and in all tissues (Steller and Pirrotta, 1984; Spradling, 1986). It has a low basal expression coupled with high inducibility (>100-fold at 42 °C) (Huynh and Zieler, 1999). The promoter is not only functional in *Drosophila* cells but also in mosquito and lepidopteran cell lines (Zhao and Eggleston, 1999; Helgen and Fallon, 1990; Lan and Riddiford, 1997).

While the *hsp70* promoter has been used to mediate expression of membrane proteins (Shotkoski *et al.*, 1996) and to drive expression of "helper" antibiotic resistance genes for the establishment of

permanently transformed cell lines (Lycett and Crampton, 1993; Vanden Broeck *et al.*, 1995) and transgenic mosquitoes (Miller *et al.*, 1987), its application for the inducible expression of proteins at high levels for functional or structural characterization is considered limited. Long-term exposure to high temperature, which is considered necessary to reach the highest expression levels, is generally detrimental to the cell cultures. Also the translational induction to heat shock is reported to be much lower than the transcriptional induction (Cherbas *et al.*, 1994), presumably because the heat shock interferes with posttranscriptional processing and translation.

Heat shock (*hsp70*) promoter-based reporter and expression constructs were also incorporated in baculovirus vectors to monitor infection of tissues and cells and to achieve protein production. In the context of the baculovirus genome in infected cells, however, gene expression from the *hsp70* promoter was constitutive rather than heat-inducible (Lee *et al.*, 2000; Moto *et al.*, 2003).

4.14.3.4.2. Metallothionein promoter Transcription of mammalian and *Drosophila* metallothionein genes is activated by heavy metal load via activation of the metal-responsive factor 1 (MTF-1) (Zhang *et al.*, 2001). Inducible expression of genes via the metallothionein promoter is achieved in *Drosophila* S2 cells and other dipteran cell lines (Johansen *et al.*, 1989; Kovach *et al.*, 1992; Millar *et al.*, 1995; Hegedus *et al.*, 1998). Protein expression via the metallothionein promoter is induced by the addition of cadmium or copper ions (10–1000 μM) and induction levels of several 100-fold are achieved (Bunch *et al.*, 1988; Otto *et al.*, 1987; Zhang *et al.*, 2001). The metallothionein promoter-based inducible system is considered suitable for the inducible expression of many different classes of proteins in dipteran cell lines.

A disadvantage of the metal ion-inducible expression system is that at the high metal ion concentrations required for achieving the highest expression levels, toxic effects are also observed on the cells, such as cytoplasmic vacuolization and granule formation as well as an associated reduction in their growth rate (Bunch *et al.*, 1988). Thus, optimal protein production requires determination of the right balance between degree of induction of gene expression and general cellular toxicity.

While the metal ion-mediated induction works efficiently in *Drosophila* and mammalian cell lines (Zhang *et al.*, 2001), in lepidopteran cell lines such as Sf9, Ld652Y, and Bm5, the metallothionein promoter was either not or only marginally functional (Hegedus *et al.*, 1998; V. Douris, L. Swevers and K. Iatrou, unpublished observations).

4.14.3.4.3. Ecdysone-inducible promoters Many insect tissue culture cell lines are sensitive to the insect molting hormone 20-hydroxyecdysone (20E) and respond to it by morphological changes and a decline in growth rates (Sorbrier *et al.*, 1989; Sohi *et al.*, 1995; Smagghe *et al.*, 2003). At the molecular level, 20E exerts its actions by binding to the ecdysone nuclear receptor (EcR) that exists as a heterodimer with the nuclear receptor Ultraspiracle (USP) (Thomas *et al.*, 1993; Yao *et al.*, 1993; Swevers *et al.*, 1996) and the hormone-bound complex directly activates transcription at ecdysone-response elements (EREs) in promoters of target genes (Antoniewski *et al.*, 1996; Vogtli *et al.*, 1998; Wang *et al.*, 1998; see **Chapter 3.5**). Early-response genes, which are directly regulated by the EcR/USP complex, are induced in insect cell lines after challenge with 20E (Sohi *et al.*, 1995; Chen *et al.*, 2002; Swevers *et al.*, 2003b), indicating that all transduction elements for gene activation by 20E are present.

Basal reporter cassettes that contain multiple repeats of an ERE derived from the *Drosophila hsp27* promoter are 1000- to 2000-fold induced by μM quantities of 20E in *Drosophila* S2 cells as well as *Bombyx*-derived (lepidopteran) Bm5 cells (Koelle *et al.*, 1991; Swevers *et al.*, 2003b). The induced expression levels are comparable to those obtained by strong constitutive promoters (Swevers *et al.*, 2003b) and silk moth (lepidopteran) transformed cell lines incorporating an ecdysteroid-inducible expression system have been described for production of recombinant proteins (Tomita *et al.*, 2001) as well as high-throughput screening for potential 20E agonists and antagonists (Swevers *et al.*, 2003b).

An advantage of the ecdysteroid-inducible expression system is that, in the absence of ligand, the EcR/USP heterodimer functions as a repressor of gene transcription (Tsai *et al.*, 1999) and the basal expression levels in the absence of the inducer are very low. Because 20E is a natural hormone, toxicity effects on the cell cultures are virtually nonexistent. Nevertheless, it remains to be investigated in detail whether the physiological effects of 20E on the function of the cells could potentially interfere with their capacity for protein production. It is expected that this will not be the case: using the baculovirus/lepidopteran cell line expression system, it was reported that the addition of ecdysteroids actually increased recombinant protein production (Sarvari *et al.*, 1990).

4.14.3.5. Classes of Recombinant Proteins Expressed by Transformed Insect Cells

4.14.3.5.1. Secreted proteins A variety of heterologous secreted proteins have been expressed from stable insect cell lines at similar or higher expression levels than can be obtained using baculovirus expression vectors (Table 2). Certainly the cellular or early-phase baculovirus promoters employed are not as transcriptionally powerful as late- and very late phase promoters such as those of the polyhedrin, p10 or basic protein genes. However, the fact that the cell's secretory pathway is not being damaged in the absence of viral infection, contributes to the improvement in the expression level and quality of the overexpressed protein compared to expression using recombinant baculovirus. The substitution of the native mammalian signal peptide coding sequence in a heterologous mammalian gene with a sequence encoding an insect-specific signal peptide was found to have no effect on the resulting expression level in transfected insect cells (Farrell *et al.*, 2000).

4.14.3.5.2. Membrane proteins As with secreted proteins, the absence of viral infection may provide a superior cellular environment for the production of membrane proteins which also traverse the secretory pathway. Several functional membrane proteins have been successfully expressed in stable insect cell lines including ion exchangers (Szerenscei *et al.*, 2000), transmitter gated ion channels (Joyce *et al.*, 1993; Millar *et al.*, 1994; Smith *et al.*, 1995; Atkinson *et al.*, 1996; Buckingham *et al.*, 1996), and GPCRs (Kleymann *et al.*, 1993; Swevers *et al.*, 2003a; see **Chapter 5.5**). As found with the baculovirus expression system (Bouvier *et al.*, 1998), coupling of heterologous GPCRs with endogenous insect G proteins may be inefficient following ligand binding, even in transformed insect cells (Figure 6). However, a strategy that has proven useful for the functional expression of heterologous GPCRs is the coexpression of mammalian G proteins in stably transformed insect cells (L. Swevers, K. Iatrou, E. Morou, N. Balatsos, and Z. Georgoussi, unpublished data; see also further below).

4.14.3.5.3. Intracellular proteins The use of transformed insect cells for the expression of intracellular proteins is of limited potential compared to the baculovirus expression system. There are a few reports on the concentrations of intracellular proteins obtained, however the promoters employed in stable gene expression from insect cells are considerably weaker than those utilized in baculovirus expression vectors (Jarvis *et al.*, 1990; Percival *et al.*, 1997; Pfeifer *et al.*, 1997). Furthermore, the purification of heterologous intracellular proteins, expressed at relatively low levels inside insect cells, from endogenous cellular protein mixtures is expected to be difficult. Secretion of the intracellular protein would facilitate the purification process. However, the mere fusion of an insect-specific signal peptide to the N-terminus of an intracellular protein failed to provide the means necessary to secrete intracellular proteins (Farrell *et al.*, 2000). It was realized that other biological signals in addition to a signal peptide are required for efficient secretion from insect and mammalian cells into an extracellular environment. These could be supplied by fusing the complete coding sequence of a secreted protein to that of an intracellular protein (Figure 7; Farrell *et al.*, 2000). The chimeric proteins produced are soluble and can be easily purified from

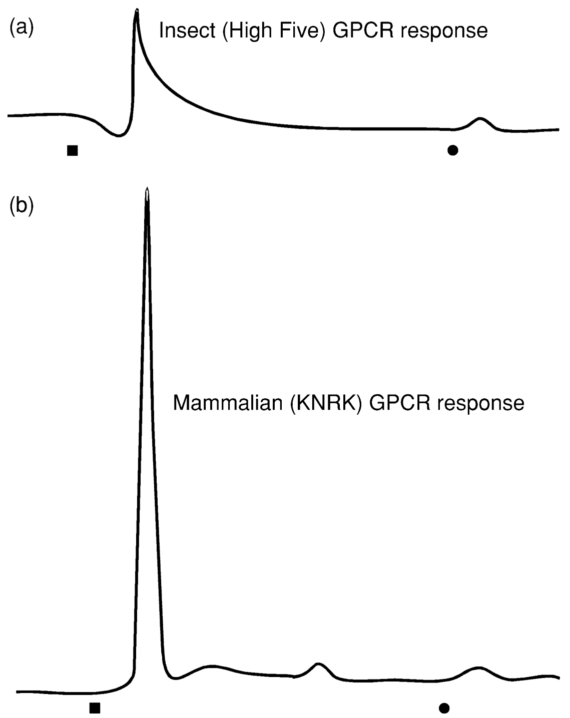

Figure 6 Fluorescent spectrophotometer outputs of calcium signaling assays to compare the G protein-coupled receptor (GPCR) response of a mammalian GPCR, the rat protease activated receptor 2 (rPAR2; Hollenberg *et al.*, 1996), expressed in stably transformed insect (panel a, High Five^{TM}) and mammalian (panel b, KNRK) cell lines. The amplitude reflects elevations in intracellular calcium with time, following exposure to the rPAR-2 peptide agonist, SLIGRL, at the time points denoted by the filled square and circle. Despite the fact that the receptor density was higher in the insect cell line (data not shown), the results imply that this mammalian GPCR does not couple well with the endogenous insect G proteins. Courtesy of Dr Morley Hollenberg, Mamoud Saifeddine and Bajhat Al-Ani (University of Calgary, Canada).

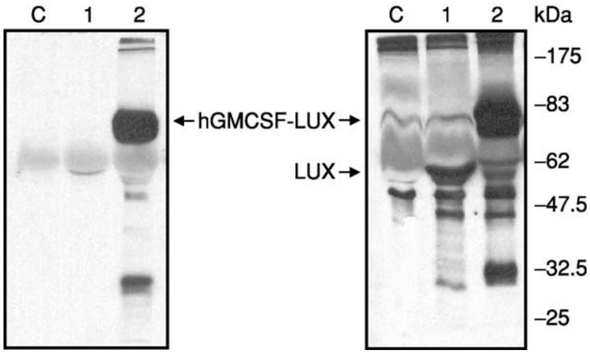

Figure 7 Secretion of luciferase from lepidopteran insect cells transfected with the pIE1/153A expression plasmid that encompasses a luciferase secretion module. Normally, luciferase (LUX) is expressed intracellularly, however, by fusing it with a secreted protein, in this case the human granulocyte macrophage colony stimulating factor (hGMCSF), the normally intracellular protein can be dragged into the supernatant as a chimera. High Five cell culture supernatants are shown in the SDS-PAGE/Western blots probed with (left) an anti-hGMCSF antibody and (right) an anti-LUX antibody. The lane marked ''C'' contains protein from a control transfection using the pIE1/153A expression vector without inserted transgene. Lanes 1 contain supernatants from cells transfected with vector pIE1/153.lux directing intracellular expression of luciferase, and Lanes 2 contain supernatants from cells transfected with vector pIE1/153A.hgmcsf-lux directing the secretion of the overexpressd hGMCSF-LUX fusion protein. Although some luciferase does leak from the cells naturally, a large proportion is secreted when expressed as a hGMCSF-LUX fusion protein.

the cell culture supernatant under nondenaturing conditions.

4.14.4. Insect Cell-Based High-Throughput Screening Systems

In cell-based detection systems, cell lines are engineered such that they respond to a biological stimulus by the generation of an easily detectable, fluorescent or luminescent, signal. Accordingly, cell-based detection systems integrate two relevant genetic elements, (1) an expression element that directs expression of the target molecule (e.g., a receptor) thus allowing the cells to respond specifically to bioactive compounds (e.g., ligands) that interact specifically with the target and initiate a downstream cell signaling response, and (2) a reporter element that allows the cells to generate an easily measurable response (fluorescent or luminescent signal) following activation of the expressed receptor by the bioactive compound.

Insect cell-based high throughput screening systems have been developed for two major types of receptors, nuclear hormone receptors (see **Chapters 3.4–3.6**) and membrane-anchored GPCRs (see **Chapter 5.5**). Because nuclear hormone receptors activate directly transcription at specific target sites in the DNA (Gronemeyer and Laudet, 1995), detection of nuclear receptor activation occurs by induction of expression of appropriate fluorescent (GFP or its variants) or luminescent (luciferase) reporter genes. On the other hand, GPCRs, which are subdivided into several classes according to the type of signal transduction pathway that they generate at the plasma membrane (cAMP up- or downregulation, release of Ca^{2+}, activation/inhibition of ion channels) (Hamm, 2001; Marinissen and Gudkind, 2001) require different reporter assays that are designed according to the specificity of each receptor class. Since the release of Ca^{2+} can be easily measured by fluorescent (e.g., employing the Ca^{2+}-sensitive fluorescent dyes fura-2 or fluo-3) or bioluminescent (coelenterazine/aequorin-based) methods (Grynkiewicz *et al.*, 1985; Knight *et al.*, 1991), activation of GPCRs that naturally function by Ca^{2+} release can be monitored by the detection of Ca^{2+} accumulation. For other GPCRs, the possibility exists to coexpress them with the mammalian $G\alpha_{16}$ protein, which can couple GPCRs of other transduction classes to the Ca^{2+} pathway (Kostenis, 2001).

4.14.4.1. Nuclear Receptors: The Ecdysone Receptor

Of the approximately 20 nuclear hormone receptors identified in the insect (*Drosophila* or *Anopheles*) genome (Adams *et al.*, 2000; Zdobnov *et al.*, 2002; see **Chapters 3.5** and **3.6**), only one has a clearly identified ligand. This is EcR, the receptor for the insect moulting hormone 20E (Escriva *et al.*, 1997). Because many insect cell lines express functional EcR receptors (Sohi *et al.*, 1995; Chen *et al.*, 2002; Swevers *et al.*, 2003a), they have the potential to be developed as screening systems for the 20E hormone (see **Chapter 3.4**).

A microplate-based bioassay, for the detection of 20E mimetic (agonistic and antagonistic) activities, was described that is based on changes in growth or morphology of the *Drosophila* B_{II} tumorous blood cell line (Clement *et al.*, 1993). This cell line is used to screen natural products from plants and fungi as well as collections of synthetic ecdysteroid derivatives for moulting and antimoulting hormone activity (Dinan *et al.*, 1997; Harmatha and Dinan, 1997; Dinan *et al.*, 2001; Harmatha *et al.*, 2002).

Another, more recently developed high throughput screening system for 20E agonists and antagonists, is based on silk moth-derived Bm5 cells that have been engineered to incorporate an ecdysteroid-responsive GFP reporter cassette in their genome

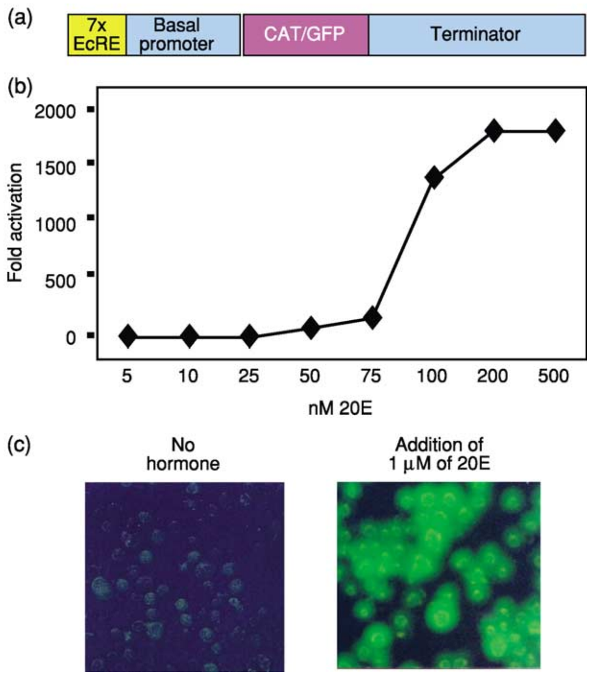

Figure 8 Establishment of a high-throughput screening system for ecdysone agonists and antagonists based on transformed silk moth-derived Bm5 cells. (a) Schematic presentation of the ecdysone-responsive reporter constructs. EcRE, ecdysone-responsive element; CAT, chloramphenicol acetyl transferase; GFP, green fluorescent protein. (b) Dose-response curve of the ecdysone-responsive CAT reporter construct in transient expression experiments. Shown is the fold inducibility in function at different hormone concentrations. (c) Induction of green fluorescence by 20E in a clonal transformed cell line that contains integrated copies of the ecdysone-responsive GFP reporter construct in their chromosomes.

(Swevers *et al.*, 2003b; **Figure 8**). The half-maximal response of activation of the reporter cassette is elicited by concentrations of 20E between 50 and 100 nM, which are comparable to the concentrations required for induction of morphological or growth inhibitory responses in other cell lines (Cherbas *et al.*, 1980; Dinan *et al.*, 1997). An important advantage of the ecdysteroid-responsive fluorescent cell lines is that the amount of fluorescence emitted by the cells can be easily detected and quantified from cells seeded in multiwell plates by a fluorescence plate reader, thus rendering the system amenable to high-throughput analysis. The ecdysteroid-inducible fluorescent Bm5 cell lines were used successfully to screen a collection of plant extracts as well as a chemical library of potential nonsteroidal agonists (dibenzoyl hydrazine derivatives) for detection of 20E agonist and antagonist activities (Swevers *et al.*, 2003b). The dibenzoyl hydrazine compounds selected by the high-throughput assay were also effective in larval toxicity tests, thus validating the usefulness of the fluorescent screening system for rapid selection of 20E mimics as potential new insecticides.

4.14.4.2. G Protein-Coupled Receptors

The majority of signal transduction by hormones or neurotransmitters is mediated by GPCRs (Vanden Broeck, 2001). In the two insects whose complete genome sequence is known, *D. melanogaster* and *Anopheles gambiae*, GPCRs comprise the largest number of genes, accounting for 1–2% of the total gene number (Hill *et al.*, 2002). Similarly, in the human genome more than 600 GPCR genes have been identified. Human GPCRs are considered important targets for drug development, and it is estimated that up to 40–50% of the available drugs are modulators of GPCR function (Kostenis, 2001).

Using the AcNPV-based baculovirus expression system, several types of mammalian GPCRs have been successfully expressed in *S. frugiperda* Sf9 and *T. ni* Hi5 cell lines (Vasudevan *et al.*, 1992; Ng *et al.*, 1995, 1997; Zhang *et al.*, 1995; Wehmeyer and Schulz, 1997; Ohtaki *et al.*, 1998). While the AcNPV-based expression system is not amenable to high throughput screening development because the cells are lysed at the end of the infection cycle, these studies nevertheless demonstrated that the receptors that were overexpressed were functional and could couple efficiently to downstream signaling elements such as ion channels and the adenylate cyclase system. Thus, using plasmid-based expression systems that do not result in cell lysis (Farrell *et al.*, 1998), transformed cell lines can be obtained that express constitutively functional GPCRs for screening of ligand mimetics.

Drosophila Schneider 2 cells have been used by several research groups to achieve permanent and functional expression of insect as well as mammalian GPCRs (Joyce *et al.*, 1993; Kleymann *et al.*, 1993; Millar *et al.*, 1995; Tota *et al.*, 1995; Vanden Broeck *et al.*, 1995; Buckingham *et al.*, 1996; Torfs *et al.*, 2000; Perret *et al.*, 2003). In the case of a tachykinin receptor from the stable fly *Stomoxys calcitrans*, activation resulted in the detection of Ca^{2+} release by fluorescent and luminescent methods, thus making the transformed cell line an effective system for the screening of tachykinin-like ligands (Torfs *et al.*, 2002).

In mammalian cell-based screening systems, the "promiscuous" Gα proteins, $G\alpha_{15}$ and $G\alpha_{16}$, have been used to couple the activation of any GPCR to the Ca^{2+} signaling pathway (Stables *et al.*, 1997; Kostenis, 2001). The presence of the $G\alpha_{16}$ protein results in the activation of phospholipase Cβ

(PLCβ) resulting in the production of the secondary messengers diacyl glycerol (DAG) and inositol (1,4,5)-triphosphate (IP_3). While DAG activates other downstream pathways through activation of protein kinase C, the action of IP_3 results in the release of Ca^{2+} from intracellular stores (Stables *et al*., 1997), which can be subsequently detected easily by fluorescent or bioluminescent methods (Grynkiewicz *et al*., 1985; Knight *et al*., 1991). Cell lines overexpressing $G\alpha_{16}$ protein can, therefore, be used to screen for ligands of GPCRs that normally couple to other second messenger or to ion channels.

This strategy has been employed recently in the case of transformed silk moth Bm5 cells that overexpress the murine δ opioid receptor: coexpression of the human $G\alpha_{16}$ protein in these cells has resulted in the stimulation of the coupling of the mouse receptor to the PLCβ/IP_3 pathway, thus making the transformed cell line a very effective screening system for ligands of the δ opioid receptor (L. Swevers, K. Iatrou, E. Morou, N. Balatsos and Z. Georgoussi, unpublished data).

4.14.5. Glycosylation of Recombinant Proteins in Insect Cells

Considerable attention has been paid to the glycosylation patterns of heterologous recombinant proteins produced in insect cells, particularly N-linked glycosylation. Several excellent and comprehensive reviews in this area have been published by Jarvis *et al*. (1998), Altmann *et al*. (1999), Marchal *et al*. (2001), and Jarvis (2003). In these reviews, it is agreed that oligomannose (five to nine mannose residues; Altmann *et al*., 1999) and fucosylated trimannose type carbohydrate (Jarvis *et al*., 1998) moieties dominate the N-linked glycosylation pattern of heterologous secreted and membrane proteins expressed in insect cells. The lack of complex glycosylation, such as the presence of terminal sialic acid found on many mammalian glycoproteins, excludes the use of insect cells to express mammalian glycoproteins for some applications. One solution to this limitation is to engineer baculoviruses (Jarvis *et al*., 1996; Wagner *et al*., 1996) or insect cell lines (Hollister *et al*., 1998) to express mammalian glycotransferases necessary for complex glycosylation of an over-expressed protein. The coexpression of two mammalian glycotransferases, β-1,4-galactosyltransferase and α-2,6-sialyltransferase, enabled an insect cell for the first time to produce an artificially sialylated baculovirus glycoprotein gp64 (Seo *et al*., 2001). This research will almost certainly extend the utility of insect cells to the production of "mammalized" complex glycoproteins.

4.14.6. Conclusions and Future Perspectives

Baculoviruses and insect cell lines have acquired a significant biotechnological niche for the production of proteins of general scientific and pharmaceutical value. While baculovirus vectors provide a superior system for high level expression of intracellular proteins, their use for the production of proteins that require an intact cellular environment is considered to be suboptimal. In contrast, the recently developed expression systems that employ baculovirus-derived genetic elements and direct continuous high level expression in transformed insect cells, not only circumvent the major drawbacks of the baculovirus expression systems for secreted and membrane-anchored proteins but can also be employed as high-throughput screening tools for the identification of bioactive substances with defined biological specificities.

For the baculovirus system, great technical improvements have occurred, mostly with regard to the efficiency and ease of generating recombinant viruses, with the best case being the generation of recombinant viruses through direct cloning into bacterially isolated bacmid chromosomal DNA. Because of the high degree of sophistication already achieved, relatively little improvement in this system is expected in the coming years. By contrast, the use of plasmid-based expression systems for insect cells is relatively recent and important improvements and new applications are expected to arise in the future.

Plasmid-based expression systems are not, in general, considered optimal for the production of intracellular proteins, because their isolation requires cell lysis and purification from a multitude of contaminating cellular proteins. Improvements in the production process are expected to include the redirection of normally intracellular recombinant proteins toward the extracellular medium, from which they can be purified with relative ease, particularly if the medium is serum-free. To test this strategy, secretion modules derived from secreted proteins, such as JHE and granulocyte-macrophage colony-stimulating factor (GM-CSF), have been fused in-frame with the N-termini of intracellular proteins, such as the CAT enzyme and the BmCF1 nuclear receptor (Farrell *et al*., 2000). Efficient secretion to the extracellular medium has been reported and, because the engineered proteins also contained a histidine tag and an enteropeptidase cleavage site, single-step purification

could be achieved by metal-ion affinity binding coupled with proteolytic cleavage (Farrell *et al.*, 2000). Future modifications in this method may include the use of alternative affinity tags and proteolytic sites as well as improved versions of the secretion modules.

More recently, *Drosophila* S2 cell lines have been used as expression hosts for the purification of multiprotein complexes that are dedicated to the execution of particular cellular functions (Forler *et al.*, 2003). Key factors involved in particular cellular processes (e.g., splicing of mRNA precursor molecules, RNA quality control, nuclear export) were expressed as double-tagged proteins, while the expression of endogenous untagged proteins was suppressed by RNA interference. Tagged proteins, together with assembled interacting factors, were purified by the "tandem-affinity purification" strategy and component proteins of purified complexes were identified by Western blot and mass spectrometry (Forler *et al.*, 2003). The technique will be valuable for the characterization of multiprotein functional complexes operating in metazoan species, in general, and in insect ones, in particular.

Transformation of insect cell lines with expression constructs still represents a cumbersome process requiring selection of resistant cell clones after addition of antibiotics. It is expected, however, that alternatives to the method of selecting cells containing genomic integrants of plasmid vectors by antibiotic selection, including the use of vectors capable of directing autonomous integration into the host genome, will be developed in the immediate future. In fact, recent reports suggest that the use of a plasmid encompassing the genomic sequences of the *Junonia coenia* densovirus (JcDNV) directs autonomous genomic integration in insect cells grown in culture, as well as *in vivo*, without affecting the normal physiology of the host cells in any detectable way (Bossin *et al.*, 2003). Furthermore, it has also been reported that this system offers the additional advantage of integrated copy number manipulation through directed deletion of viral genome sequences from the expression plasmid (Bossin *et al.*, 2003). Although the production capabilities of this system have yet to be tested with specific protein models, it is anticipated that the incorporation in it of promoter systems that are in current use as drivers of recombinant protein expression in insect cells, will expand further the current capabilities and advantages of the nonlytic systems utilizing insect cells as hosts for continuous high level production of recombinant proteins over lytic ones. The major advantage of the use of the densovirus-based transformation system is the ease of selection of transformed cells by FACS analysis through the detection of red fluorescence in the cell nuclei (achieved by the nuclear expression of DsRed/viral capsid protein fusions directed by the use of the viral P9 promoter; Bossin *et al.*, 2003). Finally, the detection of efficient densovirus amplification and densovirus-derived transgene expression in *Drosophila* larval and adult tissues (Royer *et al.*, 2001) indicates that the densovirus-based transformation system is not limited to lepidopteran cell lines but can be applied to dipteran cell lines as well.

In mammalian systems, many nuclear receptors and GPCRs have been characterized at the molecular level using transformed cell lines, and this has led to the discovery of lead compounds (and drugs) that interfere specifically at very low doses with the function of the receptors. Equivalent data on insect receptors, however, are currently lacking to a great extent. Although the identification of the natural ligands for orphan insect (*Drosophila*) GPCRs is now occurring at a good pace, the identification of the relevant ligands was made possible through the use of heterologous expression systems such as transformed mammalian cell lines or *Xenopus* oocytes (Birgül *et al.*, 1999; Meeusen *et al.*, 2002; Staubli *et al.*, 2002; Johnson *et al.*, 2003). In this regard, we expect that insect cell lines would provide better host expression systems for insect GPCRs and could be employed for a more effective screening for compounds that interfere with their functions. The same applies for the identification of ligands for the approximately 20 orphan nuclear receptors that exist in the insect genome (Adams *et al.*, 2000; Zdobnov *et al.*, 2002). The transcriptional properties of several of these receptors have been characterized (e.g., the HNF-4 receptor (Kapitskaya *et al.*, 1998), the FTZ-F1 receptor (Suzuki *et al.*, 2001), and the HR3 and E75 receptors (Swevers *et al.*, 2002)) and it should be relatively straightforward to design cell-based reporter systems for screening of ligands, particularly small molecules capable of blocking their functions. In this regard, it is worth noting that the *Drosophila* DHR38/USP receptor complex was recently found to be activated by various ecdysteroids (Baker *et al.*, 2003), illustrating the as yet unrealized potential of orphan nuclear receptors as targets for interference by small molecule ligands. Thus, like their mammalian counterparts, insect orphan receptors can be considered as targets for interference by small molecules, which can be developed into environmentally friendly insecticides that function as "endocrine disruptors," and insect cell-based expression systems are anticipated to play an instrumental role in the discovery effort.

5.1 Sodium Channels

D M Soderlund, Cornell University,
Geneva, NY, USA

5.1.1. Introduction

5.1.1.1. Function and Structure of Voltage-Sensitive Sodium Channels

Voltage-sensitive sodium channels mediate the transient increase in sodium ion permeability that underlies the rising phase of the electrical action potential in most types of excitable cells (Hille, 2001). In vertebrates, sodium channels are found in neurons and cardiac and skeletal muscle cells as well as glial and neuroendocrine cells (Goldin, 2002). In contrast, voltage-sensitive sodium channels in insects appear to be limited in distribution to neurons (Littleton and Ganetzky, 2000).

The principal structural element of voltage-sensitive sodium channels is a large (~260 kDa) α subunit that forms the ion pore and confers the functional and pharmacological properties of the channel (Catterall, 2000; Yu and Catterall, 2003). Sodium channel α subunits are pseudotetrameric proteins that contain four internally homologous domains, each of which contains six hydrophobic transmembrane helices and additional hydrophobic segments that contribute to the formation of the ion pore (**Figure 1**). The four internally homologous domains form a radially symmetrical assembly with the ion pore at the center (Guy and Seetharamulu, 1986; Yellen, 1998; Lipkind and Fozzard, 2000).

Voltage-sensitive sodium channel α subunits are part of a larger family of cation channels that also includes cyclic nucleotide-gated channels and voltage-sensitive potassium and calcium channels (Strong *et al.*, 1993). Whereas voltage-sensitive sodium and calcium channels share the pseudotetrameric four-domain structure shown in **Figure 1**, voltage-sensitive potassium channels and cyclic nucleotide-gated channels are composed of four separate subunits, each of which corresponds to a single domain of sodium and calcium channels. The phylogenetic distribution of voltage-sensitive cation channels and amino acid sequence comparisons among and between channel classes suggest that the earliest channels were tetramers of four separate subunits, like voltage-sensitive potassium channels (Strong *et al.*, 1993; Goldin, 2002). These data also suggest that four-domain calcium channels arose from such channels via two rounds of intragenic duplication. The four-domain voltage-sensitive sodium channels, which appear later in evolution than calcium channels, are likely to have arisen from duplication and divergence of voltage-sensitive calcium channels.

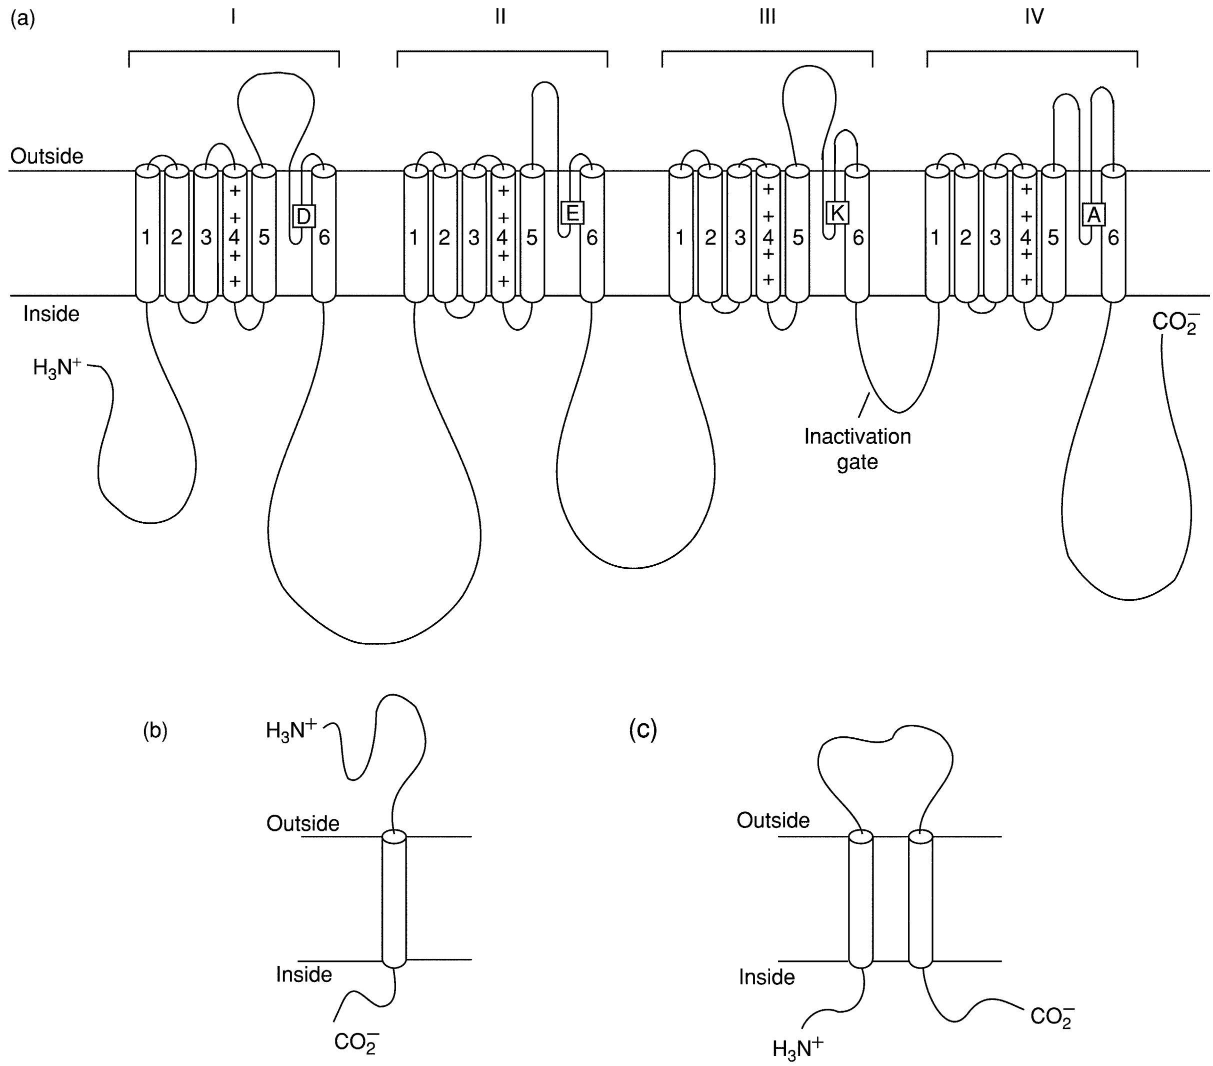

Figure 1 Diagrammatic representations of the structure of vertebrate and insect sodium channel subunits. (a) Sodium channel α subunit, showing the four internally homologous domains (I–IV), each containing six hydrophobic transmembrane helices. Also illustrated are other structural elements relevant to sodium channel function: the multiple positively charged residues (+) in the four S4 helices that constitute the voltage sensor, the four amino acids constituting the selectivity filter (the ''DEKA motif'') located in the pore-forming regions of the four internally homologous domains, and the inactivation gate peptide between the third and fourth domains. (b) Vertebrate sodium channel auxiliary β subunit. (c) Insect sodium channel auxiliary tipE subunit.

Further sodium channel gene duplication and divergence in the course of mammalian evolution has resulted in at least 10 sodium channel α subunit genes that differ in amino acid sequence, developmental and anatomical distribution, and biophysical and pharmacological properties (Goldin *et al.*, 2000; Goldin, 2002). In mammalian brain and skeletal muscle, sodium channel α subunits are associated with one or more smaller auxiliary β subunits that modulate the expression and functional properties of sodium channel α subunits (Catterall, 2000; Goldin, 2001).

5.1.1.2. Sodium Channels as Targets for Neurotoxicants

Voltage-sensitive sodium channels are the site of action of a wide structural variety of naturally occurring neurotoxins that contribute to the chemical ecology of predation and defense (Cestèle and Catterall, 2000; Blumenthal and Seibert, 2003; Wang and Wang, 2003). These sites, together with binding sites for synthetic neurotoxicants and drugs, identify at least 10 distinct binding domains associated with the voltage-sensitive sodium channel.

Five principal neurotoxin recognition sites, designated as sites 1–5 (Catterall, 1988, 1992), have been identified in both functional assays and in radioligand binding experiments (see **Table 1**). These sites are thought to represent physically non-overlapping domains of the sodium channel protein that interact allosterically as the channel protein changes conformation in response to the binding of one or more neurotoxins. Site 1 binds the water-soluble toxins tetrodotoxin (TTX) and saxitoxin (STX), which interact at or near the extracellular opening of the ion pore and block ion transport through the channel. Site 2 binds a structurally heterogeneous group of lipophilic toxins that alter both the opening (activation) and closing (inactivation) of sodium channels. Site 2 neurotoxins shift the voltage dependency of sodium channel activation toward more negative membrane potentials, thereby increasing the probability that channels will open at normal membrane resting potentials. These toxins also slow or completely block sodium channel inactivation, thereby prolonging the open state of the channel. Site 3 binds a group of polypeptide toxins, called α-toxins, isolated from scorpion venoms or sea anemone nematocysts. These toxins selectively prolong sodium channel inactivation without affecting the rate or voltage dependency of channel opening and allosterically enhance the action of compounds acting at site 2. Site 4 binds a second group of polypeptide scorpion toxins, called β-toxins, which selectively enhance sodium channel activation and do not interact allosterically with site 2 compounds. Site 5 binds the brevetoxins and ciguatoxin, lipophilic compounds isolated from marine dinoflagellates, which shift the voltage dependency of sodium channel activation and prolong inactivation in a manner similar to site 2 neurotoxins. However, these compounds bind at a site distinct from site 2 and interact allosterically with compounds acting at site 2.

Table 1 Identified and inferred binding domains on the voltage-sensitive sodium channel

Site[a]	*Active neurotoxins*[b]	*Physiological effect*
Binding domains identified with specific radioligands		
1	Tetrodotoxin	Inhibit ion transport
	Saxitoxin	
	μ-Conotoxin	
2	Veratridine	Persistent activation
	Batrachotoxin	
	Aconitine	
	Grayanotoxins	
	Pumiliotoxin-B	
	N-alkylamides	
3	α Scorpion toxins	Prolong inactivation
	Sea anemone toxins	
4	β Scorpion toxins	Enhance activation
5	Brevetoxins	Persistent activation
	Ciguatoxin	
6	δ-Conotoxins	Prolong inactivation
	Conus striatus toxin	
7	DDT and pyrethroids	Prolong inactivation
Binding domains inferred but not characterized with radioligands		
8	μO-conotoxins	Inhibit ion transport
9	Gonioporatoxin	Prolong inactivation
10	Local anesthetics	Inhibit ion transport
	Anticonvulsants	
	Antiarrhythmics	
	Pyrazolines	

[a]Sites 1–5 after Catterall (1988); sites 6 and 7 after Zlotkin (1999); sites 8–10 are assigned arbitrarily to distinguish them from sites 1–7.
[b]Insecticides are capitalized.

Subsequent research has identified two additional binding domains that are labeled with specific radioligands and shown to be distinct from sites 1 to 5. Site 6 (**Table 1**) binds δ-conotoxins and *Conus striatus* toxin (Gonoi *et al.*, 1987; Fainzilber *et al.*, 1994). Site 7 (**Table 1**) (also designated site 6 in some classifications) binds dichlorodiphenyltrichloroethane (DDT) and pyrethroids (Bloomquist and Soderlund, 1988; Lombet *et al.*, 1988; Trainer *et al.*, 1997). At least three other binding domains (arbitrarily designated as sites 8–10 in **Table 1**) have been postulated to account for the actions on sodium channels of μO-conotoxins (Terlau *et al.*, 1996), *Goniopora* coral toxin (Gonoi *et al.*, 1986), and local anesthetics, class I antiarrhythmics, and class I anticonvulsants (Catterall, 1987).

Sodium channels are widely recognized as the principal target site for diphenylethane (e.g., DDT) and pyrethroid insecticides (Sattelle and Yamamoto, 1988; Bloomquist, 1993; Soderlund, 1995; Narahashi, 1996). In addition, other toxicant-binding domains on the sodium channel are important target sites for the continued discovery and development of novel insect control agents. Two additional classes of synthetic insecticides alter sodium channel function by binding to sites that are distinct from the pyrethroid recognition site. Synthetic *N*-alkylamide insecticides, which are analogs of insecticidal natural products, produce excitatory effects by binding to site 2 (Ottea *et al.*, 1989, 1990), whereas pyrazolines (also called dihydropyrazoles) and structurally related insecticides suppress normal nerve activity by the voltage-dependent blockade of sodium channels in a manner similar to anticonvulsants (Salgado, 1990, 1992; Deecher *et al.*, 1991;

Deecher and Soderlund, 1991). The recent development of indoxacarb, the first commercial insecticide derived from pyrazoline-type compounds (Harder *et al*., 1996; Wing *et al*., 1998), underscores the continued relevance of the sodium channel as a target for insecticide development. Sodium channels are also the target of insect-selective polypeptide toxins from scorpion venoms (Zlotkin *et al*., 1995) which have been genetically engineered into insect baculoviruses; two potential biopesticide products based on this technology have proceeded to the stage of large-scale field tests (Cory, 1999).

5.1.1.3. Progress in Insect Sodium Channel Research Since 1985

The report in 1984 of the first DNA sequence for a voltage-sensitive ion channel, the voltage-sensitive sodium channel of the eel (*Electrophorus electricus*) electric organ (Noda *et al*., 1984), marked the beginning of a period of explosive growth in the application of molecular techniques to the study of ion channels that continues to the present. Since that time, studies of mammalian ion channels have identified the existence of gene families for both the α and β subunits of the voltage-sensitive sodium channel and have elucidated the structural domains of sodium channel α subunits that confer many of the biophysical and pharmacological properties of channel isoforms (Catterall, 2000; Goldin, 2001). Biomedical applications resulting from this research include the identification of sodium channel gene mutations that cause heritable diseases and a renewed interest in voltage-sensitive sodium channels as targets for therapeutic agents (Cannon, 2000; Clare *et al*., 2000; Baker and Wood, 2001; Goldin, 2001).

The corresponding expansion of information on voltage-sensitive sodium channels in insects during this period has occurred in two stages. The first of these involved the integration of molecular biology with classical genetic approaches in *Drosophila melanogaster* to further illuminate the nature of gene mutations that were implicated genetically as determinants of sodium channel function and to determine the molecular structures of the genes defined by these mutations. The second phase, in which the molecular and functional characterization of sodium channels was extended to include numerous other insect taxa, was driven principally by research to define the role of sodium channel gene mutations in insecticide resistance. This chapter reviews the literature on insect voltage-sensitive sodium channels since 1985 from both of these perspectives.

5.1.2. Sodium Channel Genes in Insects

5.1.2.1. Sodium Channel Genes in *Drosophila melanogaster*

5.1.2.1.1. *dsc1* The first putative insect sodium channel α subunit gene to be identified, *dsc1*, was isolated from *D. melanogaster* DNA libraries by low-stringency hybridization to a probe from the *E. electricus* sodium channel (Okamoto *et al*., 1987; Salkoff *et al*., 1987; Ramaswami and Tanouye, 1989). Sequence analysis of partial genomic DNA and cDNA clones identified sequences encoding the four internally homologous domains (Salkoff *et al*., 1987), but sequences of the 5′ and 3′ termini and the segments lying between homology domains I and II and homology domains II and III, all of which are regions of low sequence conservation in vertebrate genes, were not defined until the recent report of a full-length *dsc1* coding sequence (Kulkarni *et al*., 2002). The *dsc1* locus was initially mapped to cytogenetic region 60D-E on chromosome 2R (Okamoto *et al*., 1987; Salkoff *et al*., 1987; Ramaswami and Tanouye, 1989) and subsequently localized to cytogenetic region 60E5 by genome sequencing (Adams *et al*., 2000). Expression of the *dsc1* gene is under both anatomical and developmental regulation: expression in embryos and larvae is restricted to very few cells, some of which may be nonneuronal, whereas *dsc1*-derived transcripts are found at much higher levels in pupae and adults, where they are widely expressed in the central nervous system and retina (Tseng-Crank *et al*., 1991; Hong and Ganetzky, 1994). A recent genome-wide screen identified *dsc1* transcripts as targets for RNA editing at a site in the "inactivation gate" sequence (**Figure 1**) between homology domains III and IV (Hoopengardner *et al*., 2003).

Alignment of the dsc1 protein sequence with those of vertebrate sodium channels suggests that dsc1 may exhibit atypical ion selectivity. Two conserved amino acid residues, a lysine in the pore-forming region of homology domain III and an alanine in the corresponding location in homology domain IV, are crucial for the sodium ion selectivity typical of voltage-sensitive sodium channels. When either of these is mutated to a glutamate residue the resulting channel becomes permeable to calcium and other monovalent and divalent cations that normally do not permeate sodium channels (Heinemann *et al*., 1992). The dsc1 protein sequence contains a glutamate residue rather than the conserved lysine residue in the pore-forming region of homology domain III and therefore may form a channel that is permeable to calcium as well as sodium. This observation is intriguing in light of recent studies identifying a

novel sodium current in dorsal unpaired median neurons of the cockroach *Periplaneta americana* that is biophysically distinct from the more typical sodium channels present in the same neurons and is permeable to calcium as well as sodium (Grolleau and Lapied, 2000; Defaix and Lapied, 2001).

5.1.2.1.2. *para* The *para*^{ts} (*paralytic–temperature-sensitive*) locus at cytogenetic location 14D on the X chromosome of *D. melanogaster* was first identified as the site of a temperature-sensitive paralytic mutation (Suzuki *et al.*, 1971), which was subsequently found to cause temperature-sensitive impairment of action potential conduction in nerves (Siddiqi and Benzer, 1976; Wu and Ganetzky, 1980). Sequencing of genomic DNA and cDNA clones derived from the *para* locus showed that *para* encodes a protein having all of the structural hallmarks of voltage-sensitive sodium channel α subunits and exhibiting approximately 50% overall amino acid sequence identity to vertebrate sodium channel α subunits (Loughney *et al.*, 1989). The *para* gene product is quite divergent from the *dsc1* gene product in that the four conserved internal homology domains of the two *D. melanogaster* genes are only as similar to each other (~50% amino acid sequence identity) as they are to the corresponding regions of vertebrate sodium channel proteins.

Sequence analyses of partial cDNAs derived from the *para* loci of *D. melanogaster* and the related species *D. virilis* identified alternative mRNA splicing at eight sites involving seven optional exons (designated *a, b, e, f, h, i,* and *j*) and one pair of mutually exclusive exons (designated *c/d*), resulting in 256 possible unique structural variants from the *para* gene (Thackeray and Ganetzky, 1994, 1995; O'Dowd *et al.*, 1995; Warmke *et al.*, 1997). The locations of alternatively spliced exons in relation to other structural landmarks in the para protein are illustrated in **Figure 2**. Alternative splicing at

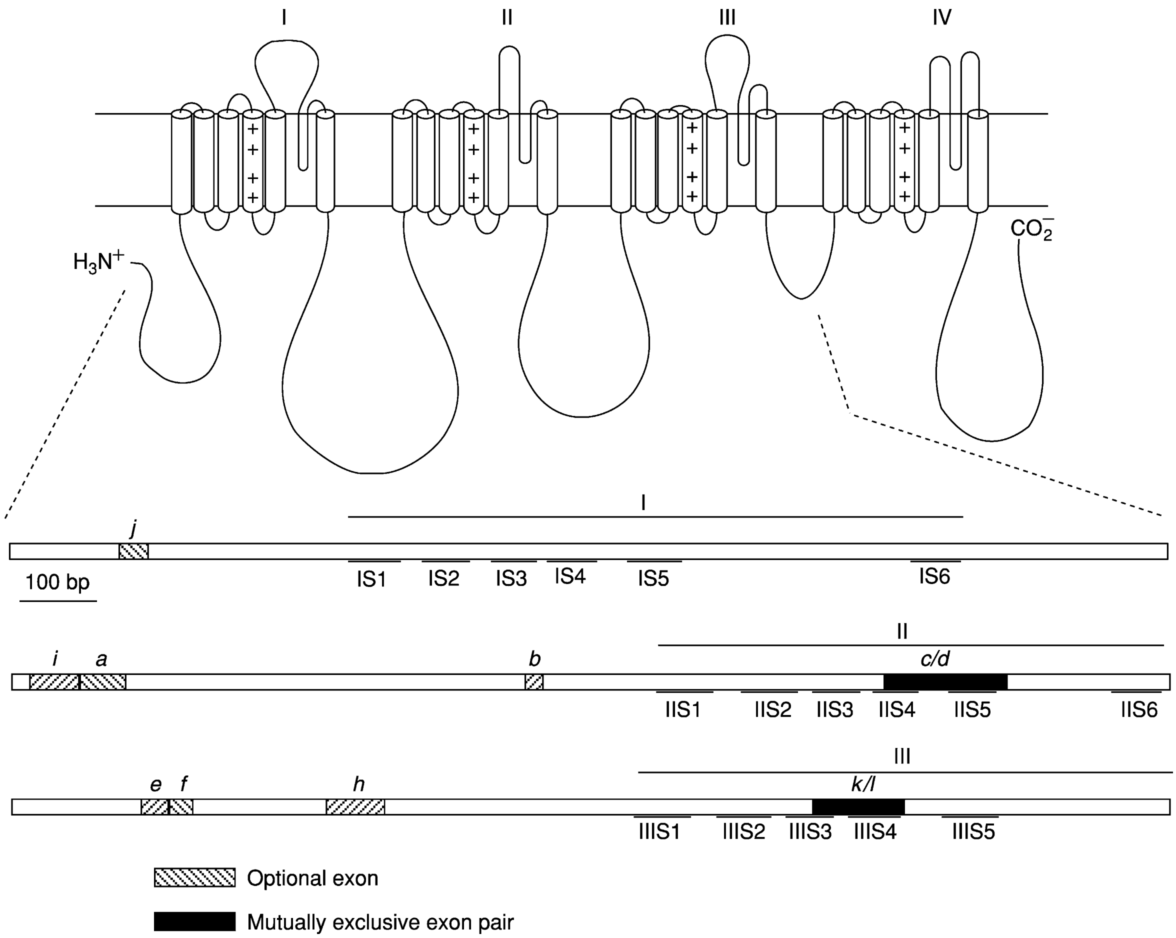

Figure 2 Diagram showing the approximate size and location of optional and mutually exclusive exons of in the *para* and *Vssc1* sodium channel genes in relation to other sodium channel structural landmarks. (Modified with permission from Lee, S.H, Ingles, P.J., Knipple, D.C., Soderlund, D.M., **2002**. Developmental regulation of alternative exon usage in the housefly *Vssc1* sodium channel gene. *Invert. Neurosci. 4,* 125–133.)

these sites produces a heterogeneous family of sodium channel α subunit transcripts. Additional transcript heterogeneity in these species is conferred by posttranscriptional RNA editing at three sites (Hanrahan *et al.*, 2000). Transcripts from the *para* locus are expressed strongly in the nervous system throughout development, but analysis of transcript pools from different developmental stages and anatomical regions revealed significant developmental and anatomical regulation of both alternative splicing and RNA editing (Tseng-Crank *et al.*, 1991; Hong and Ganetzky, 1994; Thackeray and Ganetzky, 1994, 1995; Hanrahan *et al.*, 2000).

5.1.2.1.3. *tipE* The *tipE* (*temperature-induced paralysis, locus E*) gene, at cytogenetic region 64B2, is the site of a temperature-sensitive paralytic mutation having a phenotype similar to that of *para* mutants (Kulkarni and Padhye, 1982; Jackson *et al.*, 1986; Feng *et al.*, 1995b). Sequence analysis of cDNAs derived from the *tipE* locus identified an open reading frame encoding a 452-amino acid protein that is clearly not a member of the voltage-sensitive ion channel family and exhibits no significant sequence similarity to any other proteins in sequence databases (Feng *et al.*, 1995a). The tipE protein contains two hydrophobic segments having properties consistent with the formation of transmembrane helices that flank a loop that contains five potential *N*-glycosylation sites. Transcripts from the original *tipE* mutant strain contain a premature stop codon between the two hydrophobic domains and therefore express a truncated tipE protein. Expression of the *tipE* gene in *D. melanogaster* is restricted to the nervous system and exhibits strong developmental regulation, so that transcript levels are very low in embryonic and larval stages but increase markedly in the late pupal stage. Genetic and functional criteria (see Section 5.1.3.1) suggest that the tipE protein may be a sodium channel auxiliary subunit, functionally analogous but structurally unrelated to vertebrate sodium channel β subunits.

5.1.2.1.4. Genetic and functional characterization of *D. melanogaster* mutants Gene dosage and interaction studies with $para^{ts}$ mutants provide evidence for a crucial physiological role for the para protein. Homozygous $para^{ts}$ mutants that exhibit temperature-sensitive paralysis in a wild-type background are unconditionally lethal in the presence of either nap^{ts} (*no action potential, temperature-sensitive*) or *tipE*, both of which also impair nerve function at nonpermissive temperatures (Ganetzky, 1984, 1986). Similarly, decreased dosage of $para^{+}$ is unconditionally lethal in a nap^{ts} background, but increased dosage of $para^{+}$ causes leg-shaking behavior, a sign of neuronal excitation, and suppresses the temperature sensitivity of nap^{ts} (Stern *et al.*, 1990).

The *smellblind* locus was originally identified as the site of mutations causing olfactory defects and was mapped close to *para* on the X chromosome (Lilly and Carlson, 1989). Two viable *smellblind* alleles exhibit temperature-dependent lethality to embryos at high temperatures and to adults at low temperatures, whereas four other alleles are recessive lethals (Lilly and Carlson, 1989; Lilly *et al.*, 1994b). None of the six *smellblind* alleles complements the lethality of two unconditionally lethal *para* alleles, and two of the recessive lethal alleles of *smellblind* contain rearrangements within the primary *para* transcript (Lilly *et al.*, 1994a). Taken together, these results show that *smellblind* is a novel class of *para* mutation. Interestingly, *smellblind* alleles do not exhibit the rapid, temperature-sensitive paralysis of $para^{ts}$ mutants, and the $para^{ts}$ mutants examined so far do not exhibit olfactory defects (Lilly *et al.*, 1994a).

Electrophysiological and pharmacological studies provide additional evidence for the functional importance of the *para* gene product. The temperature-sensitive failure of nerve conduction associated with $para^{ts}$ alleles is presynaptic to the cervical giant fibers, which remain electrically excitable at nonpermissive temperatures (Nelson and Wyman, 1989; Elkins and Ganetzky, 1990). Cultured neurons from embryos homozygous for different $para^{ts}$ alleles exhibit an allele-dependent reduction in sodium current density; in the case of $para^{ST76}$ the expression of sodium currents was reduced by 98% (O'Dowd *et al.*, 1989). One of these alleles, $para^{ts2}$, also caused a depolarizing shift in the voltage dependence of activation of sodium channels in cultured embryonic neurons. Cultured larval neurons from $para^{ts}$ individuals exhibit temperature-dependent resistance to veratridine, which binds to site 2 on the sodium channel and causes persistent channel activation (Suzuki and Wu, 1984). Also, several $para^{ts}$ strains are resistant to DDT and pyrethroid insecticides (Pittendrigh *et al.*, 1997).

The *tipE* mutation causes a temperature-dependent paralytic phenotype similar to that caused by $para^{ts}$ alleles (Jackson *et al.*, 1986). Three additional mutant *tipE* alleles, generated by γ-ray mutagenesis and characterized as deletions or translocations disrupting the *tipE* locus, confer the temperature-sensitive phenotype when heterozygous with the original ethylmethanesulfonate-induced *tipE* allele (Feng *et al.*, 1995b). This finding suggests that the original *tipE* mutation, identified

as a premature stop codon yielding a truncated gene product (Feng *et al.*, 1995a), is a loss-of-function mutation. In addition to conferring the conditional paralytic phenotype, the *tipE* mutation causes temperature-sensitive impairment of conduction in adult, but not larval, nerves (Ganetzky, 1986; Elkins and Ganetzky, 1990) and reductions of approximately 50% in the sodium current density of cultured embryonic neurons and in density of [^{3}H]saxitoxin binding sites in adult head preparations (Jackson *et al.*, 1986). Studies using cultured embryonic neurons show that $tipE^+$ is required for the sustained repetitive firing of sodium-dependent action potentials (Hodges *et al.*, 2002). Sodium currents in neurons from animals carrying the *tipE* mutation recover more slowly, and the minimum interpulse interval needed to produce a second full-amplitude action potential is longer, than those in neurons from wild-type animals. Expression of the wild-type $tipE^+$ transgene rescues all of the functional deficits conferred by the *tipE* mutation in these assays.

Interactions between *tipE* and $para^{ts}$ alleles provide further insight into the functional role of the tipE protein. As noted above, *tipE* interacts with various $para^{ts}$ alleles to cause unconditional lethality at temperatures that are permissive for single mutants (Ganetzky, 1986). It is interesting that some alleles of *para* exhibit partial viability when combined with *tipE*, whereas other allelic combinations are unconditionally lethal. These observations have been interpreted as evidence that the tipE and para proteins may interact physically (Ganetzky, 1986).

In contrast to the large body of information available about the functional significance of *para* and *tipE*, there is very little information on the role of *dsc1*. Embryonic neurons homozygous for a deficiency that includes the *dsc1* locus exhibit normal sensitivity to veratridine (Sakai *et al.*, 1989), thereby indicating the presence of functional sodium channels in these cells. Moreover, these neurons express voltage-sensitive sodium currents that are indistinguishable from those in wild-type cells (Germeraad *et al.*, 1992). These studies provide further evidence that *para* rather than *dsc1* encodes the sodium channels found in embryonic neurons.

Until recently, there were no mutations associated with the *dsc1* locus that might illuminate the function of the dsc1 protein. However, a series of *smell-impaired* (*smi*) mutants, created by single *P* element insertion mutagenesis and isolated on the basis of the loss of an olfactory avoidance behavioral phenotype, included one mutation (*smi60E*) mapping close to the *dsc1* locus (Anholt *et al.*, 1996). Subsequent studies showed that this mutant strain contains a *P* element transposon within the second intron of the *dsc1* gene (Kulkarni *et al.*, 2002). The reduction of olfactory avoidance behavior in this strain is correlated with a reduction in the abundance of *dsc1* transcripts, and excision of the *P* element restores wild-type behavior and *dsc1* transcript levels. These results provide the first clear indication of a physiologically defined role for the dsc1 protein.

5.1.2.2. Sodium Channel Genes in Other Insect Species

5.1.2.2.1. Orthologs of *para* The identification of the *para* gene product as a physiologically important voltage-sensitive sodium channel in *D. melanogaster* (Loughney *et al.*, 1989) and the concurrent development of the polymerase chain reaction (PCR) as a means of gene identification (Saiki *et al.*, 1988) provided the conceptual and technical framework for the isolation of *para*-orthologous DNA sequences from other arthropod species (Doyle and Knipple, 1991; Knipple *et al.*, 1991). The likely importance of voltage-sensitive sodium channels as sites of mutations conferring resistance to DDT and to pyrethroid insecticides provided further impetus for this effort (Soderlund and Knipple, 2003). As a result, full-length or partial genomic DNA or cDNA sequences now are known for *para*-orthologous sodium channel genes from at least 15 additional arthropod species.

Two concurrent and independent efforts led to the characterization of the full-length coding sequence of *Vssc1* (also called *Msc*), the *para* ortholog of the housefly (*Musca domestica*) (Ingles *et al.*, 1996; Williamson *et al.*, 1996). The inferred sequence of the Vssc1 protein is 90% identical to that of the most similar splice variant of the *para* gene product (Loughney *et al.*, 1989; Thackeray and Ganetzky, 1994). The initial sequence analyses of *Vssc1* cDNA clones obtained from adult fly heads did not identify alternatively spliced transcripts (Ingles *et al.*, 1996; Williamson *et al.*, 1996). A subsequent study investigated the issue of alternative splicing at the *Vssc1* locus in greater detail by examining the heterogeneity of multiple cDNA clones derived from *Vssc1* transcripts in three different developmental stages and two different adult body regions (Lee *et al.*, 2002). This investigation identified multiple alternative exons in the *Vssc1* gene, including a new pair of mutually exclusive exons (designated *k* and *l*) (**Figure 2**) encompassing part of transmembrane domain IIS3 and all of transmembrane domain IIS4. This splice site was not previously identified in the analysis of *para* transcripts in *Drosophila* species, which contain a segment homologous to exon *l* (Thackeray and Ganetzky, 1994, 1995; O'Dowd

et al., 1995; Warmke *et al.*, 1997), but a search of the *para* genomic sequence (Adams *et al.*, 2000) identified a segment upstream of the exon *l*-like sequence with substantial sequence similarity to exon *k* of *Vssc1* (Lee *et al.*, 2002). The amino acid sequences of exons *k* and *l* are highly divergent, differing at 16 of 41 amino acid residues, but retain conserved features of the voltage sensor structure in domain IIIS4. Other novel aspects of alternative splicing of *Vssc1* transcripts in *M. domestica* included the apparent constitutive expression of optional exons *h* and *i* and the apparent inactivation of exon *c* by a stop codon, so that all transcripts encoding full-length channel sequences contained only exon *d* at this site. Alternative splicing at all of the sites identified either in *Vssc1* or in the *para* genes of *D. melanogaster* or *D. virilis* could theoretically generate up to 512 structurally unique sodium channel splice variants. However, only a small subset of these variants (five or fewer) comprised more than 90% of the transcripts in each *M. domestica* cDNA pool examined.

The *para* ortholog of *Blattella germanica* (designated $para^{CSMA}$) encodes an inferred protein sequence that is 76–78% identical to the two dipteran sequences (Dong, 1997; Tan *et al.*, 2002a). Analysis of multiple $para^{CSMA}$ sequences identified novel aspects of alternative exon usage at some of the sites of alternative splicing found in *D. melanogaster* and *M. domestica*. For example, $para^{CSMA}$ transcripts contain two examples of segments corresponding to optional exon *j*, suggesting that the *B. germanica* gene may incorporate multiple variants of this exon. Similarly, the *B. germanica* transcripts contain three different exons (designated G1, G2, and G3) at the exon *k*/*l* splice site in homology domain III (Tan *et al.*, 2002a). Exons G1 and G2 correspond to exons *l* and *k* of *para* and *Vssc1*, whereas exon G3 exhibits no obvious sequence similarity to either exon G1 or G2 and contains an in-frame stop codon. Exon G3 corresponds exactly to an alternative exon in vertebrate $Na_v1.6$ sodium channels that contains a premature stop codon at the same position (Plummer *et al.*, 1997).

The structure of *hscp*, the ortholog of *para* in *Heliothis virescens*, was determined by sequence analyses of genomic DNA and PCR-amplified cDNA segments (Park *et al.*, 1999). The reported *hscp* coding sequence, which is incomplete at the 3′ end, gives a predicted protein sequence that is 80% identical to the corresponding coding region of *para*. Fifteen of the 19 introns identified in the *hscp* gene were conserved in location with respect to the corresponding introns in *para*, and alternatively spliced transcripts containing optional exon *j* and mutually exclusive exons *c* and *d* were detected. This study also identified several transcripts lacking sequences from the linker between homology domains I and II that contained premature stop codons. Unlike the truncation of the *M. domestica* and *B. germanica* transcripts by premature stop codons located in alternatively spliced exons, these *H. virescens* transcripts appear to be the result of splicing errors that resulted in missing exons and frameshifts.

The ortholog of *para* in the head louse, *Pediculus capitis*, encodes a voltage-sensitive sodium channel α subunit protein that is 73% identical to *para* and the *B. germanica* and *M. domestica* orthologs (Lee *et al.*, 2003). Full-length sequences from two strains of head louse and one strain of body louse (*P. humanus*) were 99.6% identical at the nucleotide level, providing further evidence that the head louse and body louse are conspecific. Analysis of multiple transcripts provided evidence for alternative splicing of a segment homologous to exon *j* of *para*. All of the transcripts contained segments corresponding to *para* optional exons *a*, *b*, and *h* and mutually exclusive exons *d* and *l* but did not contain segments corresponding to optional exons *i*, *e*, and *f*.

The ortholog of *para* in the varroa mite, *Varroa destructor* (designated *VmNa*) encodes a voltage-sensitive sodium channel α subunit that is only 51% identical to the *para* gene product of *D. melanogaster* (Wang *et al.*, 2003). Sequence analysis of multiple *VmNa* transcripts identified several novel aspects of alternative exon usage in this gene. Some *VmNa* transcripts contained an optional exon (designated exon 3) corresponding to the pair of mutually exclusive introns *k* and *l* in *Drosophila* species and *M. domestica* (**Figure 2**). Some *VmNa* transcripts also contained option exons at three sites not previously identified as sites of alternative splicing: exon 1, a segment of homology domain II containing part of the IIS2 and all of the IIS3 transmembrane helices; exon 2, a short inserted sequence in the domains II–III intracellular linker; and a retained intron in the C terminus containing an alternative stop codon. Channels lacking exon 1 or 3 would also lack critical determinants of channel organization and function and therefore may be inactive, whereas the alternative splicing of exon 2 and the alternative C terminus could be involved in the regulation of channel expression or functional properties.

Partial sequences of varying length also exist for the *para* orthologs from 10 additional arthropod species: *Anopheles gambiae* (Martinez-Torres *et al.*, 1998; Ranson *et al.*, 2000); *Bemisia tabaci* (Morin *et al.*, 2002); *Boophilus microplus* (He *et al.*, 1999); *Culex pipiens* (Martinez-Torres *et al.*, 1999a); *Frankliniella occidentalis* (Forcioli *et al.*, 2002); *Helicoverpa armigera* (Head *et al.*, 1998); *Hematobia*

irritans (Guerrero *et al.*, 1997); *Leptinotarsa decemlineata* (Lee *et al.*, 1999b); *Myzus persicae* (Martinez-Torres *et al.*, 1999b); and *Plutella xylostella* (Schuler *et al.*, 1998).

5.1.2.2.2. Orthologs of *dsc1* The search for the *para* ortholog of *B. germanica* also yielded a partial cDNA of the ortholog of *dsc1* in this species (Dong, 1997). Subsequent work described the complete coding sequence of this gene (designated *BSC1*) and identified three regions of alternative exon usage (Liu *et al.*, 2001). Reverse transcription (RT)-PCR analyses documented the expression of *BSC1* transcripts not only in the nerve cord but also in muscle, gut, fat body, and ovary, a much broader pattern of expression than was found by *in situ* hybridization of *dsc1*-derived probes to *D. melanogaster* tissues (Hong and Ganetzky, 1994). RT-PCR assays also showed that the expression of *BSC1* splice variants was both tissue-specific and developmentally regulated (Liu *et al.*, 2001). So far, the only other ortholog of *dsc1* described in the literature is a partial genomic DNA sequence from *H. virescens* (Park *et al.*, 1999).

5.1.2.2.3. Orthologs of *tipE* The *tipE* gene is of interest because of its clear involvement in modifying sodium channel expression and function and the suggestion that it may encode a novel type of sodium channel auxiliary subunit. The ortholog of *tipE* in *Musca domestica*, designated *Vsscβ*, encodes a predicted protein that exhibits 72% overall amino acid sequence identity to the tipE protein and 97% identity within the hydrophobic regions identified as probable transmembrane domains (Lee *et al.*, 2000a). These results suggest that *tipE* and *Vsscβ* are substantially more divergent in sequence than are the two sodium channel α subunit genes from these species.

5.1.3. Functional Expression of Cloned Insect Sodium Channels

5.1.3.1. Expression of Functional Sodium Channels in *Xenopus* Oocytes

Unfertilized oocytes of the African clawed frog, *Xenopus laevis*, are a powerful tool for confirming the functional roles of neurotransmitter receptors and ion channels and for correlating channel structure with functional and pharmacological properties (Lester, 1988). Oocytes injected with cRNA (synthetic mRNA prepared from cloned cDNA) express sodium channels in the cell membrane that can be detected by conventional electrophysiological assays, such as two-electrode voltage clamp analysis of the currents carried by the expressed proteins in response to changes in membrane potential or the application of native or exogenous ligands (Goldin, 1992; Stühmer, 1992). This system, coupled with site-directed mutagenesis of cloned cDNAs, has been widely employed in structure–function studies of vertebrate sodium channels (Catterall, 2000; Goldin, 2001; Yu and Catterall, 2003).

Initial efforts to express functional sodium channel from synthetic *para* cRNA injected into oocytes produced voltage-gated sodium currents of very low amplitude, but coexpression of *para* and *tipE* cRNAs stimulated sodium current expression approximately 30-fold (Feng *et al.*, 1995a). Subsequent studies (Warmke *et al.*, 1997) showed that injection of large amounts of *para* cRNA was required to obtain more robust currents in the absence of *tipE* cRNA. These authors also showed that para/tipE channels inactivated more rapidly than those expressed from *para* alone. Thus, coexpression of *para* and *tipE* reconstitutes the functional properties of the native *D. melanogaster* voltage-sensitive sodium channel and provides evidence that the tipE protein may function as a sodium channel auxiliary subunit.

Efforts to express functional sodium channels in oocytes from *Vssc1* cRNA produced results similar to those with *para*, requiring large amounts of injected cRNA to yield low levels of sodium current expression, but coexpression with *tipE* cRNA resulted in the robust expression of voltage-gated sodium currents (Smith *et al.*, 1997; Lee *et al.*, 2000a). These Vssc1/tipE channels, like para/tipE channels, inactivated more rapidly than channels expressed from either *para* or *Vssc1* cRNA alone. Coexpression of Vssc1 with its conspecific auxiliary subunit, Vsscβ, was more effective than coexpression with tipE in enhancing the level of sodium current expression and accelerating the inactivation kinetics of Vssc1 sodium channels (Lee *et al.*, 2000a). Coexpression with *tipE* cRNA was also found to be necessary for the expression of functional sodium channels from $para^{CSMA}$ cRNA in oocytes (Tan *et al.*, 2002b). However, this study did not document the expression of functional channels in oocytes from $para^{CSMA}$ cRNA alone.

5.1.3.2. Pharmacological Properties of Expressed Insect Sodium Channels

Insect sodium channels expressed in oocytes retain sensitivity to insecticides and other natural and synthetic toxicants that alter sodium channel function. Insect sodium channels expressed in oocytes also are sensitive to blockade by nanomolar concentrations of tetrodotoxin (Warmke *et al.*, 1997; Smith *et al.*,

1998; Tan *et al*., 2002a). These channels are also susceptible to modification by the alkaloid batrachotoxin (Lee and Soderlund, 2001) and polypeptide toxins from sea anemone (Warmke *et al*., 1997) and scorpion (Shichor *et al*., 2002) venoms.

The effects of pyrethroids on expressed insect sodium channels have been extensively investigated in the context of the functional characterization of sodium channel mutations associated with pyrethroid resistance (see Section 5.1.4.5). When assayed under voltage clamp conditions, type I pyrethroids (i.e., cismethrin and permethrin) appear to bind predominantly to resting or inactivated channels, shifting the voltage dependence of activation to more negative potentials and causing a slowly activating sodium current. These compounds also produce characteristic sodium tail currents following a depolarizing pulse that decay with first-order time constants (Smith *et al*., 1997, 1998; Warmke *et al*., 1997; Zhao *et al*., 2000). In contrast to these results, type II pyrethroids (i.e., [1*R*,*cis*,α*S*]-cypermethrin and deltamethrin) exhibit profound use-dependent modification of sodium currents, which implies that these compounds bind preferentially to activated sodium channel states (Smith *et al*., 1998; Vais *et al*., 2000; Tan *et al*., 2002b). The tail currents caused by these compounds are more persistent than those caused by cismethrin or permethrin. In the case of deltamethrin, tail current decay is biphasic, rather than monophasic (Vais *et al*., 2000; Tan *et al*., 2002b); this finding has been interpreted as evidence for two binding sites on insect sodium channels with different affinities for this ligand (Vais *et al*., 2000).

5.1.3.3. Functional Characterization of Sodium Channel Splice Variants

The conservation of alternative exon structure and the developmental and anatomical regulation of alternative exon usage in the *para* sodium channel gene of *D. melanogaster* and its orthologs in other insect species imply that alternative splicing may generate a family of sodium channel proteins with differing functional properties, as has been found for other ion channels and receptors (Harris-Warwick, 2000). Most of the optional exons identified in *para* orthologs to date (see **Figure 2**) are located in intracellular domains of the sodium channel protein. These exons may therefore be involved in the regulation of sodium channel expression or function as the result of interactions with protein kinases or G proteins (Cukierman, 1996; Cantrell and Catterall, 2001). This interpretation is consistent with the existence in exons *a* and *i* of consensus protein kinase A phosphorylation sites (O'Dowd *et al*., 1995; Ingles *et al*., 1996). Similarly, exons 2 and 4 of the *VmNa* sodium channel are located in intracellular domains, and exon 2 contains contains a consensus protein kinase C phosphorylation site (Wang *et al*., 2003). The sole exception so far to the intracellular location of optional exons is exon 1 of the *VmNa* sodium channel sequence, which is located in the transmembrane region of domain II (Wang *et al*., 2003).

So far, there is little direct evidence bearing on the functional significance of the alternative splicing of optional exons. In embryonic *D. melanogaster* neurons, functional sodium channels were detected only in those cells having *para* transcripts containing exon *a* (O'Dowd *et al*., 1995). This study also documented enhanced sodium current expression in cells expressing channels that contain both exons *a* and *i*. Whereas these findings imply a critical role for exon *a* alone and the combination of exons *a* and *i* together in sodium channel regulation, the direct comparison in functional expression assays using *X. laevis* oocytes of variants of *para* that differ only by the presence or absence of exon *a* did not find any effects of exon *a* on sodium current expression or properties in this system (Warmke *et al*., 1997).

In contrast to the optional exons, the mutually exclusive exons in *para* orthologs occur within the transmembrane regions of homology domains II and III (**Figure 2**). There is no information on the functional role of the alternative splicing of exons *c* and *d*. In *D. melanogaster*, these exons differ by only two of 55 amino acid residues (Loughney *et al*., 1989). In *M. domestica*, all functional channels apparently contain only exon *d* because exon *c* contains an in-frame stop codon (Lee *et al*., 2002). These observations suggest that alternative splicing at the *c*/*d* site may play a role in posttranscriptional regulation rather than in the generation of functionally distinct channel variants.

The most significant functional effects of alternative exon usage have been documented for splice variants at the exon *k*/*l* site. Unlike exons *c* and *d*, exons *k* and *l* (corresponding to exons G2 and G1 in *B. germanica*) differ substantially in amino acid sequence (Lee *et al*., 2002; Tan *et al*., 2002a). Expression of *para*^{CSMA} variants containing either exon G1 or G2 in oocytes documents differences in the voltage dependence of both activation and inactivation of these channels (Tan *et al*., 2002a). Unexpectedly, this study also found substantial differences between these variants in their sensitivity to the pyrethroid insecticide deltamethrin. These results provide the first experimental evidence for functional differences between splice variants of insect sodium channels. Alternative splicing at the *k*/*l* site in

B. germanica and *V. destructor* also appears to be involved in the expression of inactive channel variants, in that exon G3 in the *para*^{CSMA} sequence encodes a truncated channel (Tan *et al.*, 2002a) and the absence of exon 3 in the *VmNa* sequence encodes a channel lacking one of the four voltage sensor regions (Wang *et al.*, 2003).

5.1.4. Sodium Channels and Knockdown Resistance to Pyrethroids

5.1.4.1. Knockdown Resistance

The knockdown resistance (*kdr*) trait, which confers resistance to the rapid knockdown action and lethal effects of DDT and pyrethrins, was first documented in houseflies in 1951 (Busvine, 1951) and isolated genetically in 1954 (Milani, 1954). The *kdr* trait confers resistance to both the rapid paralytic and lethal actions of all known pyrethroids, as well as the pyrethrins and DDT, but does not diminish the efficacy of other insecticide classes (Oppenoorth, 1985). Electrophysiological assays employing a variety of nerve preparations from larval and adult *kdr* insects (Bloomquist, 1988) provide direct evidence for reduced neuronal sensitivity as the basis for the *kdr* trait. A second resistance trait in the housefly (designated *super-kdr*) that confers much greater resistance to DDT and pyrethroids than that found in *kdr* strains has also been isolated genetically and mapped to chromosome 3 (Sawicki, 1978; Farnham *et al.*, 1987). The *kdr* and *super-kdr* traits are widely presumed to represent allelic variants at a single resistance locus on the basis of their similar spectra of resistance and their common localization to chromosome 3 in the housefly.

Resistance mechanisms similar to *kdr* have been inferred in a number of agricultural pests and disease vectors on the basis of cross-resistance patterns and the absence of synergism by compounds known to inhibit the esterase and monooxygenase activities involved in pyrethroid metabolism (Soderlund and Bloomquist, 1990; Bloomquist, 1993; Soderlund, 1997; Soderlund and Knipple, 1999). Confirming electrophysiological evidence for reduced neuronal sensitivity to pyrethroids also exists for at least six species: *H. virescens*, *Spodoptera littoralis*, *Culex quinquefasciatus*, *A. stephensi*, *B. germanica*, and *P. xylostella* (Bloomquist, 1988, 1993; Schuler *et al.*, 1998).

Pyrethroids are known to exert their insecticidal effects by altering the function of voltage-sensitive sodium channels in nerve membranes (see Section 5.1.1.2). Therefore, studies of *kdr*-like resistance have focused on mechanisms that might affect the regulation, pharmacology, or function of the sodium channel.

5.1.4.2. Altered Sodium Channel Regulation as a Mechanism of Knockdown Resistance

The possible role of reduced insecticide receptor density in knockdown resistance was initially implicated on the basis of resistance-associated reductions in the density of binding sites for [3H]STX (Rossignol, 1988), a radioligand that specifically labels site 1 of the sodium channel (see **Table 1**). However, further investigation of [3H]STX binding in susceptible, *kdr*, and *super-kdr* housefly strains (Grubs *et al.*, 1988; Sattelle *et al.*, 1988; Pauron *et al.*, 1989) revealed that a reduction in sodium channel density is not an obligatory component of the *kdr* or *super-kdr* phenotypes of the housefly. Moreover, comparisons of *Vssc1* transcript and protein levels in susceptible and *kdr* housefly strains did not document any differences between strains (Castella *et al.*, 1997).

Although these results rule out sodium channel downregulation as the mechanism underlying the *kdr* and *super-kdr* traits in the housefly, reduced sodium channel density could, in principle, produce a *kdr*-like phenotype. The relationship between sodium channel density and *kdr*-like resistance has been evaluated directly using the *napts* strain of *D. melanogaster*, in which the density of sodium channels (measured as binding sites for [3H]STX in head membrane preparations) is approximately half that of wild-type flies (Jackson *et al.*, 1984). Flies homozygous for *nap*^{ts} exhibit modest (~threefold) resistance to the lethal effects of DDT and pyrethroids that is also evident in delayed onset of paralysis and reduced physiological sensitivity of the adult central nervous system (Kasbekar and Hall, 1988; Bloomquist *et al.*, 1989). These results suggest that if such a mechanism were present in other insects that exhibit knockdown resistance, the magnitude of resistance observed would require a profound and readily detectable reduction in sodium channel density (Grubs *et al.*, 1988). Because reductions in sodium channel density more severe than that observed in the *nap*^{ts} strain of *D. melanogaster* would be anticipated to compromise viability, it is unlikely that reduced target density can account for *kdr*-like traits that confer significant levels of resistance.

5.1.4.3. Genetic Linkage between Knockdown Resistance and Sodium Channel Genes

Two studies employed restriction fragment length polymorphisms (RFLPs) in the *Vssc1* gene coupled with discriminating dose bioassays with DDT to demonstrate tight genetic linkage (within ~1 map

unit) of the *kdr* and *super-kdr* resistance trait and the *Vssc1* gene of *M. domestica* (Williamson *et al.*, 1993; Knipple *et al.*, 1994). In addition to providing strong genetic evidence for mutations at a sodium channel structural gene as the cause of knockdown resistance in the housefly, these two studies also provided the first experimental evidence for the widely presumed allelism of the *kdr* and *super-kdr* traits in this species.

Conceptually similar approaches were employed to investigate linkage between knockdown resistance traits and *para*-orthologous sodium channel sequences in other species. In the case of *B. germanica*, knockdown resistance was tightly linked (within ~0.2 map units) to an RFLP located with the *para*-orthologous sodium channel gene (Dong and Scott, 1994). The use of RFLP markers to assess the linkage between knockdown resistance and sodium channel gene sequences in *H. virescens* (Taylor *et al.*, 1993) was complicated by the use of a strain with multiple resistance mechanisms. Nevertheless, results of these assays suggested that one component of resistance was linked to an RFLP in the *para*-orthologous sodium channel gene of this species. In *L. decemlineata* (Lee *et al.*, 1999b) and *B. tabaci* (Morin *et al.*, 2002), sequencing of DNA from individual insects of susceptible and resistant phenotypes has identified sequence variants within sodium channel coding regions that are genetically linked with resistant phenotypes. Finally, some mutant alleles of *para* that exhibit the temperature-sensitive paralytic phenotype also exhibit resistance to pyrethroids at permissive temperatures (Hall and Kasbekar, 1989; Pittendrigh *et al.*, 1997).

5.1.4.4. Identification of Resistance-Associated Mutations

The selective alteration of sodium channel pharmacology in knockdown resistant insects and the genetic linkage of knockdown resistance traits and sodium channel gene sequences provided a strong impetus for the identification and functional characterization resistance-associated mutations in insect sodium channel genes. Results of these efforts are the subject of two recent comprehensive reviews (Soderlund and Knipple, 1999, 2003).

Comparison of partial and complete sequences from 15 housefly strains representing multiple examples of susceptible, *kdr*, and *super-kdr* phenotypes consistently identified two point mutations that were associated with resistant phenotypes (Figure 3): mutation of leucine to phenylalanine at

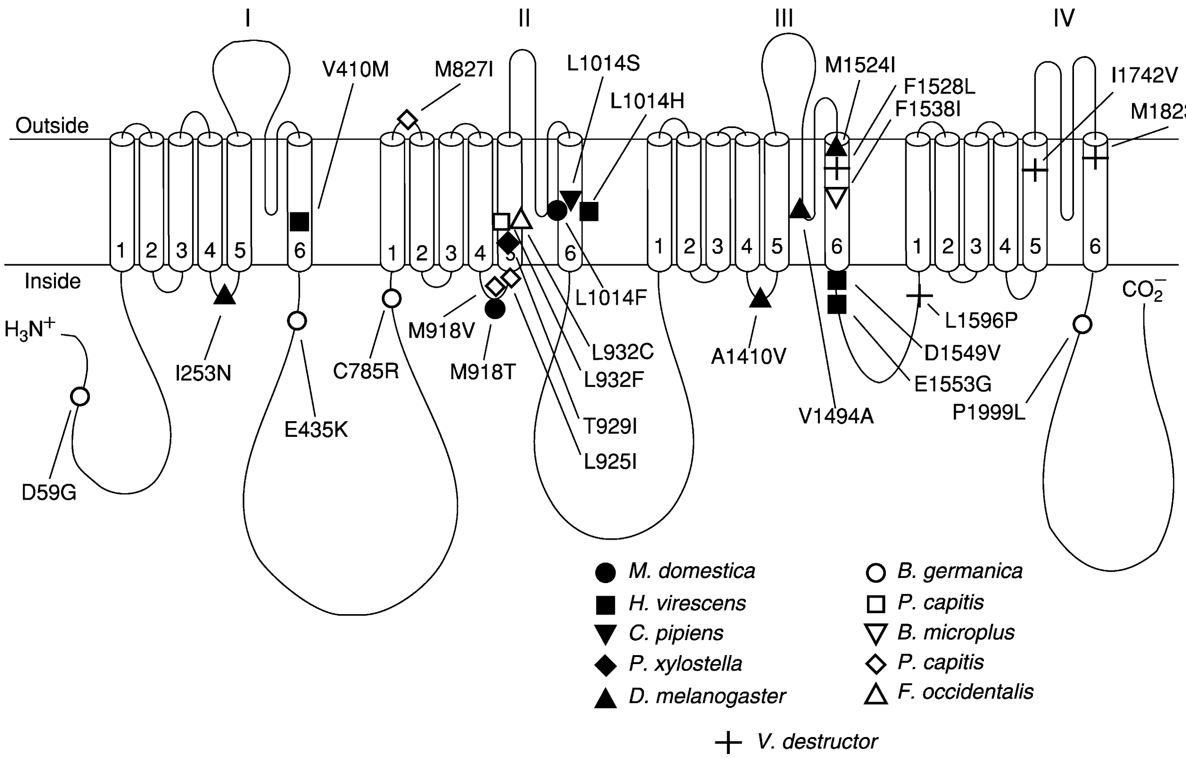

Figure 3 Locations and identities of sodium channel point mutations associated with knockdown resistance to pyrethroids. Symbols indicate the species in which each mutation was first identified (see also **Table 2**). (Modified with permission from Soderlund, D.M., Knipple, D.C. **2003**. The molecular biology of knockdown resistance to pyrethroid insecticides. *Insect Biochem. Mol. Biol. 33*, 563–577.)

amino acid residue 1014 (designated L1014F) in all *kdr* and *super-kdr* strains, and the additional mutation of methionine to threonine at residue 918 (designated M918T) only in *super-kdr* strains (Ingles *et al*., 1996; Miyazaki *et al*., 1996; Williamson *et al*., 1996). Mutations in *para*-orthologous sodium channel gene sequences corresponding to the L1014F mutation in the housefly have been also identified to date in eight additional pest species (**Table 2**): *B. germanica* (Miyazaki *et al*., 1996; Dong, 1997), *F. occidentalis* (Forcioli *et al*., 2002), *H. irritans* (Guerrero *et al*., 1997), *A. gambiae* (Martinez-Torres *et al*., 1998), *P. xylostella* (Schuler *et al*., 1998), *L. decemlineata* (Lee *et al*., 1999b), *M. persicae* (Martinez-Torres *et al*., 1999b), and *C. pipiens* (Martinez-Torres *et al*., 1999a). (For clarity and consistency and to facilitate comparisons between species, including those for which full-length sodium channel sequences are not available, all resistance-associated mutations in this report are numbered according to their positions in the amino acid sequence of the most abundant splice variant of the housefly Vssc1 sodium channel α subunit (GenBank Accession no. U38813).) In contrast to the many examples of mutations in other species corresponding to the L1014F mutation in the housefly, a mutation corresponding to the second-site M918T mutation that is associated with the *super-kdr* trait of the housefly has been found to date only in highly resistant populations of *H. irritans* (Guerrero *et al*., 1997).

The search for sodium channel gene mutations associated with knockdown resistance has also identified numerous novel mutations (**Figure 3**; **Table 2**). Studies with pyrethroid-resistant *H. virescens* populations identified a second mutation at sequence position 1014, L1014H (Park and Taylor, 1997), as well as three new mutations: V410M (Park *et al*., 1997), D1549V, and E1553G (Head *et al*., 1998). The latter two mutations were found together in sodium channel sequences from pyrethroid-resistant strains of both *H. virescens* and *H. armigera* (Head *et al*., 1998). Studies with knockdown-resistant populations of *C. pipiens* and *A. gambiae* identified a third variant at position 1014, L1014S (Martinez-Torres *et al*., 1999a;

Ranson *et al*., 2000). A novel mutation at Met918 (M918V) was recently identified in some pyrethroid-resistant *B. tabaci* populations (Morin *et al*., 2002). Characterization of sodium channel sequences from pyrethroid-resistant *P. xylostella* identified a novel putative second-site mutation (T929I) associated with the more commonly observed L1014F mutation in strains with high pyrethroid resistance (Schuler *et al*., 1998). The T929I mutation is also observed in combination with two other novel mutations, M827I and L932F, in pyrethroid-resistant *P. capitis* (Lee *et al*., 2000b, 2003). A second mutation at position 929 (T929C) was found in combination with the L1014F mutation in highly resistant populations of *F. occidentalis* (Forcioli *et al*., 2002). Recent studies with *B. tabaci* have also identified another novel mutation in this region of the sodium channel protein (L925I) that is tighly linked to pyrethroid resistance (Morin *et al*., 2002). Four novel putative second-site mutations (D59G, E435K, C785R, and P1999L) are found together with the L1014F mutation in one or more strains of *B. germanica* that exhibit high levels of pyrethroid resistance (Liu *et al*., 2000). Finally, a screen for pyrethroid resistance in strains of *D. melanogaster* having temperature-sensitive paralytic phenotypes that map to the *para* sodium channel identified four novel resistance-associated mutations: I253N, A1410V, A1494V, and M1524I (Pittendrigh *et al*., 1997).

The identification of mutations associated with pyrethroid resistance in *para*-orthologous sodium channel gene sequences also extends to noninsect arthropod species. Sodium channel sequences from populations of *B. microplus* that exhibit very high levels of pyrethroid resistance contain the F1538I mutation (He *et al*., 1999). Also, the *para*-orthologous sodium channel sequences obtained from populations of the mite *V. destructor* that are resistant to the pyrethroid fluvalinate contain four novel mutations (F1528L, P1596L, I1742V, and V1823I) (Wang *et al*., 2002), which include the first resistance-associated mutations identified in homology domain IV (**Figure 3**).

Among the 26 unique sodium channel amino acid sequence polymorphisms associated so far with pyrethroid resistance, those occurring at five sites have been found as single mutations in resistant populations: Val410 (V410M in *H. virescens*), Met918 (M918V in *Bemisia tabaci*); Leu925 (L925I in *B. tabaci*), Leu1014 (L1014F in several species, L1014H in *H. virescens*, and L1014S in *C. pipiens* and *A. gambiae*); and Phe1538 (F1538I in *B. microplus*). Mutations at six sites (M918T in *M. domestica* and *H. irritans*; T929I in *P. xylostella* and T929C in *F. occidentalis*; D59G, E435K, C785R, and P1999L in *B. germanica*) have been found in combination with the L1014F mutation in highly resistant strains and therefore have been hypothesized to function as second-site mutations that produce additive or synergistic enhancement the resistance caused by the L1014F mutation. The functional status of the remaining resistance-associated mutations is more ambiguous.

5.1.4.5. Functional Analysis of Resistance-Associated Mutations

The *X. laevis* oocyte expression system has been employed to characterize the effects of several resistance-associated mutations on the pyrethroid sensitivity and functional properties of expressed sodium channels. Most of these efforts have focussed on the mutations identified in sodium channels of *kdr* and *super-kdr* houseflies, but a more limited group of studies have also examined additional putative primary resistance mutations and certain putative secondary mutations. All of these studies involve the insertion of candidate mutations into wild-type sodium channel cDNAs, expression of wild-type and specifically mutated channels in oocytes, and direct comparison of the pharmacological properties of the expressed channels.

5.1.4.5.1. Functional analysis of the kdr and super-kdr mutations The effects of the L1014F mutation, the sodium channel gene mutation most commonly associated with knockdown resistance, on pyrethroid sensitivity have been examined in several sodium channel sequence contexts and with different pyrethroids as probes. Housefly Vssc1 sodium channels containing the L1014F substitution, coexpressed in oocytes with the *D. melanogaster* tipE protein, were approximately tenfold less sensitive to modification by cismethrin, a type I pyrethroid, than wild-type Vssc1/tipE channels (Smith *et al*., 1997). The L1014F mutation also accelerated the rate of decay of cismethrin-induced sodium tail currents. Similar experiments with wild type and specifically mutated *D. melanogaster* para sodium channels coexpressed with the tipE protein and deltamethrin as the test pyrethroid confirmed and extended these findings (Vais *et al*., 2000). Comparison of the actions of deltamethrin on wild-type para/tipE channels and channels containing the L1014F mutation reduced the sensitivity of expressed channels to deltamethrin approximately 17-fold and accelerated the rate of deltamethrin-induced tail current decay. More detailed analysis showed that mutated channels exhibited lower affinity for deltamethrin as well as a reduced availability of open

channel states due to enhanced closed-state inactivation. The effects of the L1014F mutation on deltamethrin sensitivity were also examined using *B. germanica* para^{CSMA} sodium channels coexpressed with tipE (Tan *et al.*, 2002b). In this study, the L1014F mutation conferred approximately sixfold resistance to deltamethrin but, unlike the results obtained with Vssc1/tipE and para/tipE channels, the reduction in pyrethroid sensitivity of mutated para^{CSMA}/tipE channels was not accompanied by an acceleration of tail current decay.

The discovery that the rat $Na_v1.8$ (also called SNS or PN3) sodium channel isoform was highly sensitive to both type I and type II pyrethroids (Smith and Soderlund, 2001) provided the opportunity to examine the impact of the L1014F mutation in a sodium channel sequence environment that is otherwise substantially divergent (i.e., only ~40% identical at the amino acid sequence level) from para-orthologous channels of insects. The L1014F mutation, introduced at the cognate conserved leucine residue of the rat $Na_v1.8$ channel, reduced the sensitivity of expressed channels to cismethrin more than tenfold and increased the rate of decay of the cismethrin-induced tail current. These effects were qualitatively identical to the effects of the L1014F mutation on the cismethrin sensitivity of Vssc1/tipE channels (Smith *et al.*, 1997).

The effects of the M918T mutation in the presence of the L1014F mutation, the combination of mutations associated with the *super-kdr* resistance trait of the housefly, have also been examined in both insect and mammalian sodium channel sequence contexts with both type I and type II pyrethroids as probes. Incorporation of the M918T and L1014F mutations into the Vssc1 protein gave rise to Vssc1/tipE channels that were completely insensitive to both cismethrin and [1*R*,*cis*,α*S*]-cypermethrin at the highest concentrations that could be achieved given the low aqueous solubility of these compounds (Lee *et al.*, 1999c). Similarly, rat $Na_v1.8$ sodium channels containing the M918T/L1014F double mutation were completely insensitive to modification by the highest attainable concentration of cismethrin (Soderlund and Lee, 2001). In the para/tipE sequence context the M918T/L1014F double mutation decreased the sensitivity of expressed channels to deltamethrin approximately 100-fold and also produced tail currents with monophasic, rather than biphasic, decay kinetics (Vais *et al.*, 2000). The latter effect was interpreted as evidence that the double mutation reduced the number of deltamethrin binding sites per channel from two to one.

The effects of the M918T single mutation on pyrethroid sensitivity has also been evaluated in multiple sequence contexts. Insertion of the M918T mutation into para/tipE channels gave channels that were twofold more resistant to deltamethrin than the doubly mutated (M918T/L1014F) channels; the M918T channels also exhibited monophasic tail current decay kinetics (Vais *et al.*, 2001). Insertion of the M918T mutation in Vssc1/tipE sodium channels significantly impaired sodium current expression in oocytes and produced channels that were not detectably modified by cismethrin (Lee *et al.*, 1999c). In rat $Na_v1.8$ channels, the M918T mutation caused a degree of resistance to cismethrin that was equivalent to that caused by the single L1014F mutation (Soderlund and Lee, 2001). These results suggest that the M918T mutation does not enhance resistance caused by the L1014F mutation in an additive or synergistic manner but rather provides a high level of resistance that supercedes the effect of the L1014F mutation alone.

In light of the profound reduction in pyrethroid sensitivity caused by the M918T single mutation in these assays, it is surprising that it has not been identified as a single mutation in pyrethroid-resistant insect populations. A likely explanation for this situation has emerged from studies of alternative exon usage in *para* and its orthologs (see Sections 5.1.2.1.2 and 5.1.2.2.1). In the *para* sequence of *D. melanogaster*, the Met918 residue occurs in mutually exclusive exons *c* and *d*, each of which is incorporated into a subpopulation of sodium channel sequence variants (Thackeray and Ganetzky, 1994). Exons homologous to exons *c* and *d* of *D. melanogaster* are also found among transcripts from the *para*-orthologous sodium channel gene of *H. virescens* (Park *et al.*, 1999) and *C. pipiens* (Martinez-Torres *et al.*, 1999a). In these situations, two independent point mutations (one each in exons *c* and *d*) would be required to insure that all channel variants contained the M918T substitution. In contrast, exon *c* in the housefly *Vssc1* gene contains a stop codon, so that all full-length *Vssc1* transcripts are derived solely from exon *d* (Lee *et al.*, 2002). Thus, a single point mutation in exon *d* of the housefly is sufficient to insure that all functional sodium channel splice variants in this species contain the M918T substitution. This interpretation suggests that the M918T mutation and other mutations at this site (such as the M918V mutation in *B. tabaci*) can only be selected in species in which alternative splicing at the exon *c*/*d* locus produces functional channels from only one of these alternative exons. Although consistent with available data on alternative splicing at the *Vssc1* locus in the housefly, this analysis does not explain the absence of the single M918T mutation in resistant strains of

this species. It therefore remains possible that a functional deficit associated with the M918T mutation is somehow complemented or rescued by the presence of the L1014F mutation (Lee *et al*., 1999c).

5.1.4.5.2. Functional analysis of other putative primary resistance mutations The effects of the V410M mutation, a single mutation associated with knockdown resistance in some *H. virescens* populations, has been examined in para/tipE, Vssc1/tipE, and para^{CSMA}/tipE sodium channels expressed in oocytes. Insertion of the V410M mutation into para/tipE channels resulted in a >10-fold reduction in permethrin sensitivity coupled with a ~45-fold acceleration in the rate of sodium tail current decay (Zhao *et al*., 2000). Similar results were obtained in Vssc1/tipE channels containing the V410M mutation, which decreased channel sensitivity to cismethrin by ~20-fold and accelerated the rate of tail current decay ~10-fold (Lee and Soderlund, 2001). In para^{CSMA}/tipE channels, the V410M mutation caused ~17-fold resistance to deltamethrin (Liu *et al*., 2002). In contrast to the effects of this mutation on the kinetics of channel modification by permethrin and cismethrin, resistance to deltamethrin in para^{CSMA}/tipE channels containing the V410M mutation was not accompanied by a significant acceleration in tail current decay kinetics. Although Met410 occurs in a region of the sodium channel known to be involved in the binding and action of batrachotoxin, the V410M mutation did not affect the potency of batrachotoxin as a modifier of Vssc1/tipE sodium channels in oocytes (Lee and Soderlund, 2001).

The V410M mutation is the only resistance mutation that has been examined both in the oocyte expression system and in its native cellular context. Assays with cultured adult central neurons from *H. virescens* homozygous for the V410M mutation documented a ~21-fold reduction in permethrin sensitivity of sodium channels in the resistant strain (Lee *et al*., 1999a). Although these authors did not report the time constants for the decay of permethrin-induced sodium tail current, inspection of their data suggests that reduced permethrin sensitivity in cultured neurons was apparently not correlated with a significant acceleration of tail current decay as was observed in some of the studies of the V410M mutation in oocytes (Zhao *et al*., 2000; Lee and Soderlund, 2001). In cultured neurons, channels containing the V410M mutation were approximately 2.6-fold more sensitive to the polypeptide scorpion toxin LqhαIT (Lee *et al*., 1999a).

The characterization of mutations at Leu1014 was expanded to include the L1014H mutation, another single mutation found in some knockdown-resistant *H. virescens* populations (Zhao *et al*., 2000). Incorporation of the L1014H mutation into para/tipE sodium channels conferred >tenfold resistance to permethrin, a type I pyrethroid. Permethrin-induced sodium tail currents recorded from channels containing the L1014H mutation decayed 57-fold more rapidly than those carried by wild-type para/tipE channels.

The effects of the F1538I mutation, identified in pyrethroid-resistant populations of *B. microplus*, have been assessed only in rat $Na_v1.4$ sodium channels that were also mutated to enhance baseline pyrethroid sensitivity (Wang *et al*., 2001). Deltamethrin caused use-dependent modification of these rat $Na_v1.4$ sodium channels. However, introduction of the F1538I mutation into these channels caused a loss of use-dependent modification by deltamethrin as well as a reduction in sensitivity to this compound.

5.1.4.5.3. Functional analysis of putative secondary mutations The effects of the T929I mutation, a putative second-site resistance mutation in *P. xylostella* and *P. capitis*, has been examined in para/tipE sodium channels expressed in oocytes (Vais *et al*., 2001). As a single mutation, the T929I substitution reduced the sensitivity of para/tipE channels to deltamethrin approximately tenfold. Deltamethrin-induced tail currents carried by channels containing the T929I mutation decayed rapidly with first-order kinetics. Channels containing both the T929I and L1014F mutations, the combination found in highly resistant populations of *Plutella xylostella* were more than 10 000-fold resistant to deltamethrin when compared to wild-type channels.

The effects of the E435K and C785R mutations, putative second-site mutations identified in several highly resistant *B. germanica* populations, on pyrethroid sensitivity have been examined in para^{CSMA}/tipE channels singly, together, and in combination with two primary resistance mutations. Channels containing the C785R mutation alone were identical to wild-type para^{CSMA}/tipE channels in their sensitivity to deltamethrin, but channels containing E435K single mutation and the E435K/C785R double mutation were more sensitive to deltamethrin than wild-type channels (Tan *et al*., 2002b). When either the E435K or C785R mutations were combined with the L1014F resistance mutation, the resulting double mutants were approximately 20-fold less sensitive to deltamethrin than channels containing the single L1014F mutation and approximately 100-fold less sensitive than wild-type para^{CSMA}/tipE channels. Channels

containing all three resistance mutations, a situation found in highly resistant *B. germanica* populations, were more than 500-fold less sensitive to deltamethrin than wild-type channels.

In a companion study, the E435K and C785R mutations were also evaluated as modifiers of deltamethrin resistance conferred by the V410M mutation (Liu *et al.*, 2002). Insertion of either the E435K or C785R mutation into $para^{CSMA}$/tipE channels containing the V410M mutation did not significantly affect the level of resistance conferred by the V410M mutation, but channels containing all three resistance mutations were approximately sixfold less sensitive to deltamethrin than channels containing only the V410M mutation and 100-fold less sensitive than wild-type $para^{CSMA}$/tipE channels.

5.1.5. Conclusions

5.1.5.1. Unique Features of Insect Sodium Channels

Although sodium channel function and structure is strongly conserved between evolutionarily divergent animal species, the molecular characterization of insect sodium channels has identified several distinctive features. First, in contrast to the family of sodium channel α subunit genes in mammalian species, insects appear to have only a single gene (*para* in *D. melanogaster* and its orthologs) that encodes voltage-gated, sodium-selective channels that are involved in action potential generation. However, insects are capable of generating a remarkable diversity of sodium channel variants from this locus by alternative exon usage and RNA editing. The number of sodium channel variants generated by these posttranscriptional modifications found in any given species appears to be only a fraction of the theoretical maximum, and the patterns of exon usage do not appear to be strongly conserved between species. So far there is scant information on the functional significance of alternative exon usage.

Insects also lack the sodium channel β subunit family of vertebrates and instead appear to use a novel family of glycoproteins, encoded by the *tipE* gene of *D. melanogaster* and its orthologs, as sodium channel auxiliary subunits. Genetic and cytochemical localization studies with *D. melanogaster* imply that the tipE protein is restricted in expression to the adult nervous system, suggesting that it may function as a modulator of sodium channel function and expression rather than as an obligatory auxiliary subunit. So far only two examples of *tipE*-like genes have been described, but their broader existence in insects is inferred by the heterologous coassembly of the *D. melanogaster* tipE protein with the *para*-orthologous sodium channel gene of *B. germanica*. It will be of interest to determine the breadth of distribution of *tipE*-like genes in the Insecta and in other animal taxa.

Finally, insect genomes also contain a second sodium channel α subunit-like gene, *dsc1* of *D. melanogaster* and its orthologs, that is equally divergent from the *para*-like sodium channel genes of insects and the vertebrate sodium channel α subunit gene family. The dsc1 protein is clearly not the sodium channel principally responsible for nerve action potential generation or the primary target for sodium channel-directed insecticides, and it may lack the stringent selectivity for sodium ions that is a hallmark of typical voltage-sensitive sodium channels. The functional significance of dsc1 and homologous proteins has remained obscure, but recent studies point to an as-yet undefined role in chemosensory pathways.

5.1.5.2. Sodium Channels and Pyrethroid Resistance

Molecular and genetic studies over the past decade have provided convincing evidence that point mutations in insect voltage-sensitive sodium channel genes are the primary cause of knockdown resistance to pyrethroids. Genetic linkage experiments and targeted DNA sequencing studies have consistently identified resistance-associated mutations in sodium channel genes that are orthologous to the *para* gene of *D. melanogaster.* Heterologous expression assays have documented the ability of many of these mutations, introduced into wild-type insect sodium channels either alone or in the combinations found in highly resistant populations, to reduce the sensitivity of expressed channels to pyrethroids exemplifying the type I and type II structural classes. Finally, the magnitude of resistance conferred by these mutations in heterologous expression assays *in vitro* has consistently been found to be in good agreement with the magnitude of resistance observed in resistant insect populations carrying the same mutations. These results not only identify the molecular mechanism of the *kdr* trait but also provide important confirmation that sodium channels encoded by the *Vssc1* gene are the principal target site for the toxic actions of DDT analogs and pyrethroids. Although the actions of DDT and pyrethroids on sodium channels have been characterized in great depth and detail over the past three decades, numerous other sites of action for some or all of these insecticides have also been proposed (Soderlund and Bloomquist, 1989; Bloomquist, 1993). The toxicological impact of the knockdown

resistance mutations in *para*-orthologous sodium channels implies that actions of DDT and pyrethroids at this target alone are sufficient to account for the toxic effects of these compounds in whole insects.

The search for sodium channel gene mutations in knockdown-resistant strains of various arthropod species has revealed the existence of resistance-associated polymorphisms at an unanticipated diversity of sites. Although not all of these polymorphisms have been shown to cause pyrethroid resistance, the multiplicity of sodium channel sequence polymorphisms associated with knockdown resistance contrasts with the situation for cyclodiene resistance in insects, which involves a mutation at a single amino acid residue in the subunit of the γ-aminobutyric acid receptor–chloride ionophore encoded by the *Rdl* gene in all cases that have been examined (ffrench-Constant, 1994). The diversity of sequence polymorphisms that are potentially involved in knockdown resistance poses a significant challenge for the use of this information in pyrethroid resistance monitoring and management.

The surprisingly large number of amino acid residues implicated as sites of resistance-causing mutations also poses challenges for the use of these mutations to map the pyrethroid binding site on the sodium channel. Not all of these residues are likely to interact physically with the pyrethroid molecule; mutations at some sites may indirectly alter the architecture of the pyrethroid site by altering or restricting the conformational flexibility of the sodium channel protein. As shown in **Figure 3**, most putative resistance mutations are located in the S5 and S6 helices and closely associated regions. Current models of sodium channel structure (Guy and Seetharamulu, 1986; Yellen, 1998; Lipkind and Fozzard, 2000) place the S5 and S6 domains in close proximity to each other adjacent to the inner pore of the channel. In this context, the clustering of a large number of resistance-associated mutations in the S5–S6 region of homology domain II implies an important role for this region of the sodium channel in determining, either directly or indirectly, the binding of pyrethroids. Recently, the crystal structure of a simple bacterial potassium channel was employed to generate a three-dimensional model of the S5–pore–S6 regions of the rat $Na_v1.4$ voltage-sensitive sodium channel (Lipkind and Fozzard, 2000). The use of such a model to identify the spatial relationships among the resistance-associated mutations in insect sodium channels may clarify the functional role of these residues in pyrethroid binding and action.

5.1.5.3. Future Exploitation of the Sodium Channel as an Insecticide Target

Despite the long and widespread use of DDT and then pyrethroids in the control of pests and disease vectors and the existence of knockdown resistance traits in populations of many pest and vector species, the pyrethroids remain an important and effective class of insecticides. Moreover, three key factors contribute to the continued value of the sodium channel as a target for future insecticides. First, toxicologically relevant sodium channels in insects are the products of a single gene and therefore exhibit conserved pharmacology in all neuronal tissues and insect life stages. Second, the value of sodium channel disruption as a mode of insecticidal action is amply demonstrated by the efficacy of sodium channel-directed natural toxins and insecticides. Third, toxin binding sites on the sodium channel other than the pyrethroid site (see **Table 1**) appear to be unaffected by mutations that confer pyrethroid resistance. In this context, each sodium channel binding domain can be envisioned as a separate potential target for insecticide discovery and development.

These factors in favor of the continued exploitation of sodium channels for insect control are counterbalanced by the evolutionary conservation of sodium channel structure, function, and pharmacology across animal taxa. Intrinsic selectivity of agents for insect sodium channels is uncommon, and the development of novel insecticides directed toward this target is complicated by the potential for toxicity to nontarget species. The example of pyrethroids is instructive in this regard: the notable safety of pyrethroids for humans is based principally on differential metabolism rather than differential target sensitivity, and the use of pyrethroids has been limited in some contexts by undesirable toxicity to aquatic vertebrate and invertebrate species. The development of indoxacarb, which exploits differential metabolic bioactivation as a mechanism of selective toxicity, illustrates the potential for the discovery of novel sodium channel-directed insecticides that exhibit acceptable safety and selectivity.

5.2 The Insecticidal Macrocyclic Lactones

D Rugg, Fort Dodge Animal Health, Princeton, NJ, USA
S D Buckingham and D B Sattelle, University of Oxford, Oxford, UK
R K Jansson, Centocor, Malvern, PA, USA

5.2.1. Discovery

The naturally occurring avermectins and milbemycins are fermentation products of actinomycetes in the genus *Streptomyces*. They are 16-membered, macrocyclic lactones, which have structural similarities to antibacterial macrolides and antifungal polyenes but lack their antifungal or antibacterial activities and do not inhibit protein or chitin synthesis (Fisher and Mrozik, 1989). Avermectins are produced by the soil microorganism, *Streptomyces avermitilis* MA-4680 (NRRL 8165), which was first isolated at the Merck Research Laboratories in 1976 from a soil sample collected near a golf course in Japan by researchers at the Kitasato Institute (Campbell *et al*., 1984). Milbemycins were first described from a culture of *S. hygroscopicus* and are structurally similar to the avermectins but lack the disaccharide substituent at C13 (Takiguchi *et al*., 1980). Mishima *et al*. (1975) first reported the acaricidal activity of milbemycins. The anthelmintic activity of these milbemycins was later elucidated following testing of individual members of the milbemycin family (Mrozik *et al*., 1983). Milbemycins were also isolated from cultures of *S. cyanogriseus* in 1984 by workers at American Cyanamid and from *S. thermoarchaensis* by Glaxo researchers (Rock *et al*., 2002).

Four homologous pairs of closely related compounds are produced through the fermentation of *S. avermitilis* MA-4680 (NRRL 8165), each pair comprising a major and minor component, usually produced in the approximate ratio of 8 : 2 (Lasota and Dybas, 1991). A mixture of one of these pairs, avermectin B_1 (>80% B_{1a} and <20% B_{1b}) commonly called abamectin, was found to be active against nematodes (Burg *et al*., 1979; Egerton *et al*., 1979), insects (Ostlind *et al*., 1979; James *et al*., 1980; Wright, 1984), and mites (Putter *et al*., 1981).

Ivermectin, the semisynthetic 22,23-dihydro derivative of avermectin B_1, was the first commercially produced avermectin, introduced in 1981 for use against a range of nematode and arthropod parasites (Jackson, 1989). Like abamectin, ivermectin is a mixture of two homologs known as

ivermectin B_{1a} (>80%) and B_{1b} (<20%) (Campbell *et al.*, 1983). The natural avermectin abamectin was introduced as an antiparasitic drug and an agricultural insecticide and miticide in 1985 (Campbell, 1989). The natural milbemycins milbenock and milbemectin have been used as an agricultural miticide (Tsukamoto *et al.*, 1995) and in canine heartworm therapy (Jung *et al.*, 2003), respectively. An oxime derivative of milbemycin has been used widely for filarid and nematode control in dogs. Moxidectin, a synthetically modified milbemycin derived from the fermentation product nemadectin (Carter *et al.*, 1988), is used for insect and helminth control in animal health applications. In 1993, doramectin was introduced, also for use in animal health. This compound was derived from an induced mutation of *S. avermitilis* (Goudie *et al.*, 1993) and is structurally closer to abamectin than to ivermectin (Shoop *et al.*, 1995). A subsequent semisynthetic derivative, selamectin (the monosaccharide oxime), is used to control insect, acarid and helminth parasites of cats and dogs (Bishop *et al.*, 2000).

A targeted analoging program around abamectin resulted in a five-step semisynthetic avermectin, emamectin, in 1984 (Cvetovich *et al.*, 1994). MK-243 (the hydrochloride salt of emamectin) was discovered after screening several hundred avermectin derivatives in an *in vivo* screen using tobacco budworm, *Heliothis virescens* and southern armyworm, *Spodoptera eridania* (Dybas and Babu, 1988; Dybas *et al.*, 1989; Mrozik *et al.*, 1989; Mrozik, 1994). This compound was subsequently selected for further development for control of lepidopterans in crop protection. Synthesized aglycon derivatives of ivermectin have been reported to be potent flea insecticides (Cvetovich *et al.*, 1997), but have not been developed commercially.

Numerous papers have been published on the avermectins and milbemycins (Kornis, 1995). Several authors have reviewed the discovery, structure–activity relationships, environmental fate, spectrum of activity, and applications for their anthelminthic, insecticidal, and acaricidal activity (Campbell *et al.*, 1984; Fisher and Mrozik, 1984, 1989, 1992; Davies and Green, 1986; Strong and Brown, 1987; Dybas, 1989; Lasota and Dybas, 1991; Mrozik, 1994; Kornis, 1995; Shoop *et al.*, 1995; Fisher, 1997; Jansson and Dybas, 1998; Vercruysse and Rew, 2002a). In this chapter the chemistry, mode of action, biological activity, and applications of macrocyclic lactones, with special emphasis on their use as insecticides are reviewed.

5.2.2. Chemistry

5.2.2.1. Chemical Structure

The chemical structure of avermectin B_{1a} is shown in **Figure 1**. The milbemycins share a similar basic 16-carbon lactone but lack the disaccharide moiety of the avermectins (e.g., moxidectin) (**Figure 2**). These compounds have strong ultraviolet absorption at 245 nm, a feature which is of value in analytical detection. Avermectins and milbemycins are highly lipophilic, being soluble in most organic solvents but almost insoluble in water (Fisher and Mrozik, 1989). Milbemycins tend to be more lipophilic than avermectins (Hennessy and Alvinerie, 2002). Ultraviolet light rapidly decomposes

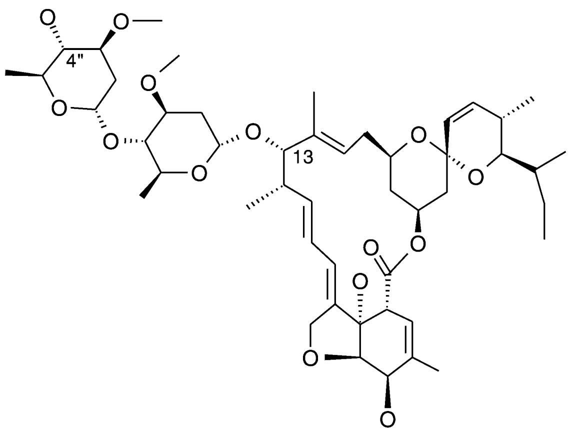

Figure 1 Chemical structure of avermectin B_{1a} (major component of abamectin).

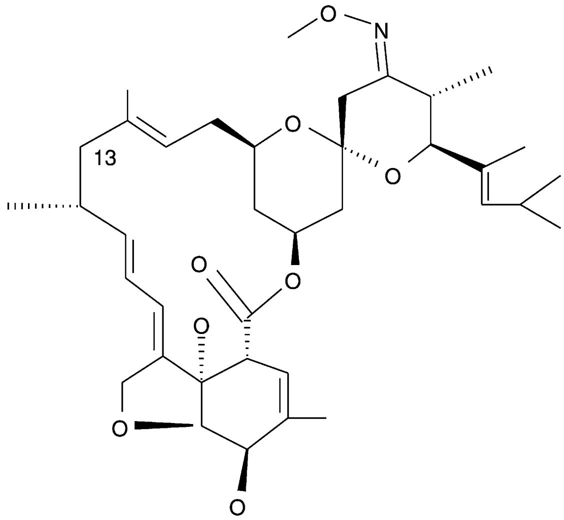

Figure 2 Chemical structure of moxidectin.

avermectins, leaving a large number of less toxic products (Halley *et al.*, 1989a) that lack any ultraviolet absorption (Mrozik *et al.*, 1988) as a residue. The half-life of ivermectin, exposed to sunlight as a thin film on glass, is about 3 h (Halley *et al.*, 1989b).

Ivermectin B_{1a} differs from abamectin in the loss of the 22,23 double bond, so that 22 and 23 are dihydrocarbons. The B_{1b} components differ from their respective B_{1a} structures by the replacement of a CH_2CH_3 group with a CH_3 (Fisher and Mrozik, 1989). Ivermectin is also commonly referred to as 22,23-dihydroavermectin B_1. Emamectin, an epimethyl amino substitution at the 4″ position of the sugar (**Figure 3**) was derived from abamectin using a five-step synthesis (Cvetovich *et al.*, 1994).

Doramectin was generated via a biosynthetic program. Mutated strains of *S. avermitilis* were used to generate novel avermectins (Goudie *et al.*, 1993). Doramectin (**Figure 4**) was selected for development as an endectocide (a compound that controls both internal and external parasites) from a number of compounds that differed from avermectins in

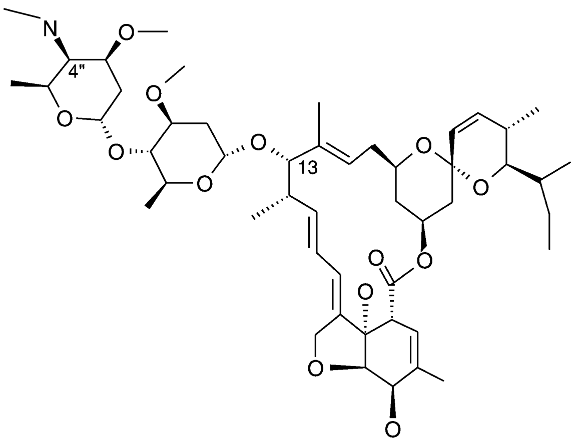

Figure 3 Chemical structure of emamectin.

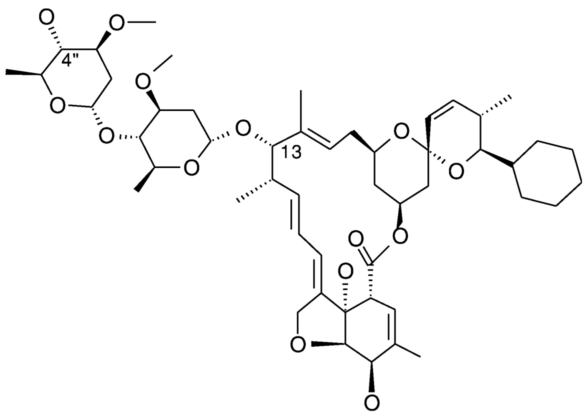

Figure 4 Chemical structure of doramectin.

substituents at the C25 position. Selamectin was chosen from a targeted chemistry research program aimed at identifying an avermectin that retained anthelminthic activity but with enhanced insecticidal activity, especially against fleas (Banks *et al.*, 2000).

Targeted synthesis programs with milbemycins have also led to commercial products. Moxidectin (**Figure 2**) was synthesized from the natural milbemycin Fα (nemadectin) via a multistep process (Carter *et al.*, 1988).

5.2.2.2. Structure–Activity Relationships

Structure–activity relationships of the avermectins and milbemycins are complicated due to the broad spectrum of activity against arthropods and helminths. However, reviews of the relationship between the activity of these compounds and chemical structure have shown some consistent patterns (Shoop *et al.*, 1995; Fisher, 1997). The major structural difference between avermectins and milbemycins is the lack of the disaccharide moiety at position C13 of the macrolide ring. Within avermectins, removal of the distal sugar results in a slight decrease in activity against nematodes. Removal of both sugars results in an avermectin aglycone with a hydroxy group at the C13 position with little useful activity against arthropods or helminths (Chabala *et al.*, 1980). When the oxygen is removed from the C13 position, the resultant deoxyavermectins recover potency and are structurally equivalent to milbemycins (Mrozik *et al.*, 1983; Shoop *et al.*, 1995). Generally, avermectins and milbemycins with lipophilic substituents at C13 are highly active, while polar substituents result in a loss of activity (Mrozik *et al.*, 1989). Similar structure–activity patterns have been seen with insects and mites.

For insecticidal activity, the most dramatic development was the synthesis of 4″-epi-amino avermectins (Fisher, 1997). In these compounds, the replacement of the hydroxy group on the distal sugar with an epimethylamino group resulted in a marked increase in potency against a variety of lepidopterans and reduced activity against mites.

5.2.3. Mode of Action

5.2.3.1. Biochemical and Molecular Action

Avermectins are potent endectocides. Ivermectin, the first and most commercially important member of this class, is the world's most successful animal health drug of all time (Raymond and Sattelle, 2002). While the molecular mode of action of avermectins initially proved difficult to define (Jackson,

1989), more recent evidence indicates that they act primarily on glutamate-gated chloride channels of helminths and insects, with additional effects (especially at high concentrations) on γ-aminobutyric acid (GABA) receptors.

Early evidence for GABA receptors as a site of action came from studies performed mostly on insects (Sattelle, 1990). Dihydroavermectin B_{1a}-sensitive GABA-binding sites were identified in the cockroach *Periplaneta americana* using [^{3}H]GABA binding (Lummis and Sattelle, 1985). Furthermore, avermectins were shown to act as a partial agonist at a GABA-binding site in honeybees (*Apis mellifera*) defined by [^{3}H]muscimol binding (Abalis and Eldefrawi, 1986). Deng and Casida (1992) examined the interactions of radiolabeled avermectin with nerve membranes from housefly (*Musca domestica*) heads and hypothesized that avermectins may either have multiple binding sites at each chloride channel, or may bind to GABA-gated channels at low concentrations and at other chloride channels at higher concentrations.

Evidence from vertebrate studies also pointed to GABA receptors as a site of action. Administered to rats, ivermectin acts as a GABA-ergic anxiolytic drug (Spinosa *et al*., 2002). Another study compared the potency of 25 avermectin analogs using a mouse seizure model with their direct action on recombinant $GABA_A$ receptors (Dawson *et al*., 2000). Interestingly, while their binding affinities to brain membrane and to recombinant $GABA_A$ receptors stably expressed in cell lines were found to be closely similar, suggesting $GABA_A$ receptors as the target, the rank order of affinity of these analogs at the [^{3}H]ivermectin binding site differed from that of their anticonvulsant activities, suggesting that their activities differed between subtypes of $GABA_A$ receptor. When the binding of the analogs to cell lines expressing known combinations of $GABA_A$ receptor subunits were measured, only modest differences in affinity (up to fivefold) were observed, compared to differences in anticonvulsant activity in the seizure model of up to 40-fold. Furthermore, their efficacy in potentiating GABA-evoked currents in *Xenopus laevis* oocytes expressing $GABA_A$ receptors correlated well with their anticonvulsant activity. The conclusion drawn, as reported earlier (Arena *et al*., 1993), was that the GABA receptor β subunit is a key determinant of avermectin potency. The study also suggested the presence of two distinct avermectin binding sites. Arena *et al*. (1993) had observed that there are twice as many avermectin binding sites as benzodiazepine sites correlating well with there being two β subunits in many $GABA_A$ receptors (Sigel and Buhr, 1997).

Certain evidence also suggested that avermectins act at sites other than $GABA_A$ receptors. For example, [^{3}H]22,23-dihydroavermectin-B_1 binding sites that were GABA-insensitive were identified in membrane preparations from *Caenorhabditis elegans* (Schaeffer and Haines, 1989). Tanaka and Matsumura (1985) found that avermectin stimulated chloride ion uptake in cockroach (*P. americana*) leg muscle; they suggested that this was not due to activity at the GABA binding site but rather a direct action on the chloride ion channel. Tanaka (1987) determined that abamectin and milbemycin act directly on a neuronal chloride channel of *P. americana*, and that this action could not be accounted for in terms of action on the GABA, picrotoxinin, or benzodiazepine sites on GABA-gated chloride channels. Nicholson *et al*. (1988) also deployed *P. americana* in studies of acetylcholine release from a central nervous system synaptosome preparation. The authors concluded that avermectins acted on a non-GABA-mediated chloride channel, with the resultant depolarization of the nerve terminal leading to increased acetylcholine release. Avermectin B_{1a} and moxidectin inhibited binding of 4-*n*-propyl-4′-ethnylbicycloorthobenzoate (EBOB) a noncompetitive blocker of the GABA-gated chloride channel in *Drosophila melanogaster* and *D. simulans* (Cole *et al*., 1995). Their efficacy in displacing EBOB was unaffected by the A302S mutation in the cloned *D. melanogaster* GABA receptor, RDL, that reduces sensitivity to convulsants, suggesting that either the main site of action of avermectin B_{1a} is not RDL, or that avermectin binding does not affect the RDL convulsant site. The dieldrin-resistant Maryland strain of *D. melanogaster*, which has the RDL A302S mutation, is susceptible to avermectin MK-243, abamectin, and abamectin 8,9-oxide (Bloomquist, 1994), again suggesting that these avermectins do not act at the convulsant site of the GABA receptor encoded by the *rdl* gene.

Evidence that glutamate-gated chloride channels are the primary site of the anthelminthic activity of avermectins came from a number of studies on nematodes. These studies showed that the interaction of avermectins with glutamate-gated chloride channels is distinct from any effect upon GABA-sensitive channels (Schaeffer and Haines, 1989; Arena *et al*., 1992, 1995). They also showed that the effects of ivermectin on its interaction with glutamate were concentration dependent. At low concentrations, ivermectin potentiated the response of the channel to glutamate, whereas at high concentrations, ivermectin opened the chloride channel directly (Arena *et al*., 1992). Thus, in nematodes, avermectins are believed to potentiate or directly open the glutamate-gated chloride channel (Arena *et al*., 1995).

Studies on cloned, expressed glutamate-gated chloride channels from nematodes and insects provide strong evidence that avermectins act upon these receptors. Cully *et al.* (1994) cloned two complementary DNAs encoding avermectin-sensitive glutamate-gated chloride channel subunits from the nematode *C. elegans*. These two genes (*GluClα1* and *GluClβ*) are newly discovered members of the cys-loop family of the ligand-gated ion channel superfamily. The α1 subunit gene is alternatively spliced to produce two subunits (Laughton *et al.*, 1997b). Cully *et al.* (1994) demonstrated that the potency of various avermectin compounds *in vivo* was correlated with their ability to potentiate glutamate-gated currents recorded when *GluClα1* and *GluClβ* are coexpressed in *Xenopus* oocytes, suggesting that these two subunits are components of the target of avermectins in nematodes. The α subunit possesses a binding site for glutamate but is not coupled to the opening of the channel (Etter *et al.*, 1996). The *GluClα1* gene is expressed in the pharyngeal muscle cells pm4 and pm5, and in some neurons (Dent *et al.*, 1997) and *GluClβ* is also expressed in pm4 (Laughton *et al.*, 1997a). When a transposon element is used to introduce a deletion in *GluClα1*, to eliminate its function, sensitivity of the animals to ivermectin remained but mRNA extracted from them and expressed in *Xenopus* oocytes resulted in the expression of glutamate receptors with reduced sensitivity to both ivermectin phosphate and to glutamate (Vassilatis *et al.*, 1997). Furthermore, in the mutant, binding of [^{3}H]ivermectin showed reduced binding affinity, indicating a loss of ivermectin binding sites. The same study also reported the cloning and functional expression of another glutamate-gated chloride channel, *GluClα2*, which when expressed in *Xenopus* oocytes responds reversibly to glutamate and irreversibly to avermectin.

Arguably, the strongest evidence that glutamate-gated chloride channels are targets for avermectins derives from genetics. Simultaneous mutation of genes encoding glutamate-gated chloride channel α-type subunits (*GluClα1*, *GluClα2*, and *GluClα3*) confers high-level resistance to ivermectin. Interestingly, only low-level (or no) resistance is conferred by mutation of any two of these three glutamate receptor genes (Dent *et al.*, 2000). It may prove to be a sound strategy to search for drug targets encoded by a multigene family because the development of drug resistance could be slower if several target genes have to be mutated simultaneously to confer resistance.

Similar results have been obtained using glutamate-gated chloride channels from other nematodes. Of the four glutamate-gated chloride channel subunits known in *Haemonchus contortus* (Delany *et al.*, 1998; Jagannathan *et al.*, 1999), two bind [^{3}H]ivermectin with high affinity when expressed in monkey kidney, COS-7, cells, which is not displaced by GABA, picrotoxin, or fipronil (convulsants that block GABA-gated chloride channels) or glutamate; and for the one channel examined, there was no difference in sequence between that from a wild-type and that from an ivermectin-resistant strain (Cheeseman *et al.*, 2001). The recently described tissue distribution of the four *H. contortus* avermectin-sensitive glutamate receptor subunits showed that these subunits are differentially expressed in the motor nervous system, as well as in other neurons (Portillo *et al.*, 2003).

Horoszok *et al.* (2001) reported the cloning of GLC-3, a glutamate-gated chloride channel from *C. elegans* that forms homooligomeric receptors when expressed in *Xenopus* oocytes. Ivermectin potently and irreversibly activated this receptor (EC_{50} the concentration that evokes a half-maximal response – 0.4 μM). The availability of a new homomeric avermectin-sensitive receptor from a helminth offers exciting possibilities for structure–function research into the site of action of these compounds.

Rohrer *et al.* (1995) identified the binding sites of ivermectin in two arthropods, *D. melanogaster* and *Schistocerca americana*. One subunit, DrosGluClα, was recently cloned from *D. melanogaster*. This subunit is sensitive to both glutamate and avermectins (Cully *et al.*, 1996). The same authors also found transcripts related to DrosGluClα in other insects, including cat flea, *Ctenocephalides felis*, fall armyworm, *Spodoptera frugiperda*, and cotton bollworm, *Helicoverpa zea*, but not in the two-spotted spider mite, *Tetranychus urticae*. It remains to be determined whether or not additional GluCl subunits are present in insects.

An exciting recent discovery may explain, in part, why avermectins appear to act at both GABA and glutamate receptors. Immunoprecipitation studies using antibodies to a *D. melanogaster* glutamate-gated chloride channel (*Dm*GluCl) showed that *Dm*GluClα antibodies precipitated all of the ivermectin and nodulisporic acid receptors solubilized by detergent from *Drosophila* head membranes, and that *Dm*RDL antibodies also immunoprecipitated all solubilized nodulisporic acid receptors and approximately 70% of the ivermectin receptors (Ludmerer *et al.*, 2002). The data led the authors to suggest that both *Dm*GluClα and RDL are components of nodulisporic acid and ivermectin receptors.

It has been suggested that avermectins may bind to a common site on all ligand-gated chloride

channels similar to the benzodiazepine site on mammalian GABA-receptors (Huang and Casida, 1997), and act in a tissue-specific manner either as positive or negative allosteric modulators. This would help to explain some of the additional effects that avermectins exert on chloride channels, such as their inhibition of strychnine binding to the mammalian glycine receptor (Graham *et al*., 1982); activation of multiple-gated chloride channels (glutamate, GABA, and acetylcholine) in crayfish (Zufall *et al*., 1989); and both potentiation and blocking of GABA-gated chloride channels in arthropods (Duce and Scott, 1985; Bermudez *et al*., 1991).

There is evidence for actions of avermectins at sites other than glutamate- or GABA-gated chloride channels. Avermectin C and avermectin A_1 increased calcium-dependent chloride currents of *Chara corallina* cells at low concentrations but blocked them at high concentrations (Driniaev *et al*., 2001). Avermectins A_2, B_1 (abamectin), B_2 and 22,23-dihydroavermectin B_1 (ivermectin) in the concentration range studied did not affect the chloride currents of *C. corallina* cells. There is also evidence for nicotinic acetylcholine receptor actions of avermectins. Ivermectin potentiates responses to acetylcholine mediated by heterologously expressed α7 nicotinic receptor subunits (Krause *et al*., 1998) with high potency (30 μM ivermectin potentiated responses to 30 μM acetylcholine (ACh) nearly threefold) through a presumed allosteric mechanism. However, responses to ACh mediated by ACR-16 (formerly known as Ce21), an α7-like homomer-forming nicotinic acetylcholine receptor subunit from *C. elegans* (Ballivet *et al*., 1996), with 47% identity with chicken α7 at the amino acid level, were not enhanced by the same concentration of ivermectin, but rather were slightly attenuated (Raymond *et al*., 2000).

In summary, avermectins affect invertebrates either by directly activating receptors for the neurotransmitters glutamate and GABA or by potentiating their actions, resulting in an influx of chloride ions into nerve cells and muscle. It appears that the anthelminthic properties of the avermectins are due predominantly to potentiation and/or direct opening of glutamate-gated chloride channels, whereas in insects, it is likely that avermectins bind to multiple sites, including both glutamate- and GABA-gated chloride channels as well as other insect chloride channels. However, not all insect chloride channels are sensitive to avermectins: one of the two chloride channels spontaneously active in cultured *D. melanogaster* larval neurons – the large conductance (35pS) "slow" channel – is insensitive to dihydroavermectin B_{1a} (Yamamoto and Suzuki, 1988). Nevertheless, there is now a wealth of evidence that the chloride ion flux resulting from the opening by avermectins of chloride channels in invertebrate nerve and muscle, particularly those gated by glutamate and GABA, results in disruption of activity and loss of function in these excitable cells and accounts for the potent endectocidal actions of these molecules.

5.2.3.2. Physiological Activity

5.2.3.2.1. Insects While avermectins are effective through both topical and oral routes in lepidopteran larvae, toxicity is generally greater through ingestion than by residual contact (Wright *et al*., 1985; Anderson *et al*., 1986; Bull, 1986; Corbitt *et al*., 1989). McKellar and Benchaoui (1996) surmised that the oral route made the major contribution to uptake of macrocyclic lactones in ectopararasitic arthropods. The higher *in vivo* activity of these compounds against sucking lice than against biting lice, and the potent effects on blood-feeding mites (Benz *et al*., 1989), supports this hypothesis. Similarly, abamectin, although having relatively poor contact activity, is potent when administered orally against cockroaches (Rust, 1986), lice (Rugg and Thompson, 1993), ants (Glancey *et al*., 1982; Baker *et al*., 1985), termites (Su *et al*., 1987), and vespid wasps (Chang, 1988).

In comparison with other neurotoxic agents, avermectins are considered to be relatively slow acting (Wright, 1986; Strong and Brown, 1987; Abro *et al*., 1988). Affected organisms usually die slowly, often over a period of days, and there is no quick knockdown effect like that achieved with the use of some pyrethroids and organophoshates (Jackson, 1989). Death usually follows paralysis and immobility. Agee (1985) described the symptoms of abamectin poisoning in *H. zea* larvae; the insects showed a gradual loss of locomotor coordination followed by lethargy and complete loss of locomotor activity. This slow action could possibly be due to either progressive paralysis of the organism's feeding, resulting in slow accumulation of the toxin, or starvation (Jackson, 1989). However, it is apparent that there is a direct neurotoxic effect, as adults of *H. zea* died more rapidly from abamectin poisoning than from starvation (Agee, 1985) and poisoned German cockroaches (*Blattella germanica*) ate less than controls, but the starved controls did not die (Cochran, 1985). The blood-sucking bug *Rhodnius prolixus* can survive for months after a blood meal, but dies within 9 days of ingestion of ivermectin (De Azambuja *et al*., 1985).

5.2.3.2.2. Acarids and helminths Symptoms of poisoning in acarids and helminths are similar to those of insects. The affected organisms cease feeding, suffer paralysis, and subsequently die (McKellar and Benchaoui, 1996). For most species, the oral route is considered the major means of uptake, although for some gastrointestinal and filarial nematodes, transcuticular absorption may be as significant as ingestion (Court *et al*., 1988).

5.2.3.2.3. Vertebrates Of the vertebrates, only fish are uniformly susceptible to macrocyclic lactone toxicity (Wislocki *et al*., 1989). Mammals are relatively insensitive to these compounds (Jackson, 1989). The signs of macrocyclic lactone poisoning in mammals are consistent with central nervous system toxicity. Symptoms include salivation, ataxia, muscle fasciculation, lingual paralysis, recumbency, apparent blindness, tremors, and depression. Lethal doses produce ataxia, convulsions, and coma (Campbell and Benz, 1984; Lankas and Gordon, 1989). These signs suggest poisoning of the central nervous system and are consistent with stimulation of GABA-gated chloride channels which are likely to be the active sites of macrocyclic lactones in mammals (Pong *et al*., 1980; Pong and Wang, 1982; Drexler and Sieghart, 1984a, 1984b, 1984c).

5.2.3.3. Sublethal Toxicity

Sublethal effects of macrocyclic lactones on insects include inhibition of feeding, developmental abnormalities, and disruption of reproduction (Strong and Brown, 1987). Cessation of feeding appears to be a symptom of toxicity as overt repellency is rarely observed with avermectins (Schuster and Everett, 1983; Cochran, 1985; Orton *et al*., 1992; Allingham *et al*., 1994). In most instances, reduction in the prolonged feeding activity of insects is due to the onset of poisoning (Strong and Brown, 1987).

Sublethal effects on development are varied. Cockroach nymphs that had been fed sublethal doses of abamectin were able to complete development (Cochran, 1985), but juvenile *R. prolixus* failed to molt (De Azambuja *et al*., 1985). Sublethal doses of abamectin fed to neonate tufted apple moth, *Platynota idaeusalis*, increased the developmental time from neonate to adult eclosion and greatly affected fecundity (Biddinger and Hull, 1999). In other lepidopterans, sublethal doses of abamectin may interfere with pupation and metamorphosis without marked disruption of larval development (Reed *et al*., 1985; Bull, 1986) and similar effects have been observed for ivermectin in dipterans (Meyer *et al*., 1980; Spradbery *et al*., 1985; Strong, 1986). Rugg (1995) found that abamectin, ivermectin, and moxidectin had some residual postfeeding effects resulting in death in the pupal stage of a dung-feeding fly, *Tricharea brevicornis*. Sublethal residues of avermectins have been shown to markedly delay the development of dung beetle larvae (Lumaret *et al*., 1993; Kruger and Scholtz, 1997) and produce morphological developmental abnormalities in dung-feeding flies (Clarke and Ridsdill-Smith, 1990; Strong and James, 1993) and dung beetles (Sommer *et al*., 1993).

Sublethal doses of these insecticides also produce various effects on reproduction. Female *R. prolixus* suffered a permanent reduction in egg production following ingestion of ivermectin (De Azambuga *et al*., 1985). In some Coleoptera, exposure to abamectin resulted in fewer eggs laid and lowered levels of hatching (Wright, 1984; Reed and Reed, 1986). Following abamectin ingestion, female *B. germanica* had fewer oocytes and produced fewer oothecae (Cochran, 1985). Also, female serpentine leafminer (*Liriomyza trifolii*) exposed to abamectin-treated leaves laid fewer eggs, possibly due to malfunction of the ovipositor after contact to abamectin (Schuster and Everett, 1983). They noted that ingestion of abamectin might have occurred and this could have an effect on toxicity to *Liriomyza*. Adult Australian blowfly *Lucilia cuprina* females fed sheep dung containing ivermectin residues show reduced fecundity, survival, and delayed reproductive development (Cook, 1991, 1993; Mahon and Wardhaugh, 1991). Orton *et al.* (1992) investigated the activity of avermectins as oviposition suppressants in *L. cuprina*. While the compounds tested were effective in suppressing oviposition, this was related to general toxic effects and was only apparent at levels that produced significant mortality. Cook (1993) found that sublethal doses of ivermectin affected mating behavior in male *L. cuprina*. The number of mating attempts was reduced and the duration of mating was longer in treated males than in nontreated males. When tsetse flies (*Glossina morsitans*) were fed on blood containing ivermectin, they aborted eggs and larvae. However, these flies produced normal larvae after refeeding on normal blood (Langley and Roe, 1984). Lepidopteran larvae treated with sublethal doses of abamectin that survived to adults displayed reduced mating, egg production, and hatching (Reed *et al*., 1985; Robertson *et al*., 1985; Wright, 1986). Sublethal doses of abamectin have been shown to irreversibly sterilize queens of the ant *Solenopsis invicta* (Glancey *et al*., 1982).

5.2.3.4. Metabolism

Oxidative metabolism is believed to be the major route for detoxification and excretion of

macrocyclic lactones in insects. Three main oxidative metabolites have been identified in mammals (Chiu and Lu, 1989; Zeng *et al.*, 1996). These metabolites are more polar than the parent compounds and greater hydrophilicity can enhance excretion of xenobiotics in insects. Studies with resistant and susceptible Colorado potato beetle (*Leptinotarsa decemlineata*) have implicated oxidative metabolism as a major mechanism in resistance to avermectins (Argentine, 1991; Argentine *et al.*, 1992; Yoon *et al.*, 2002).

5.2.4. Biological Activity

5.2.4.1. Spectrum and Potency

5.2.4.1.1. Insects The macrocyclic lactones are among the most potent insecticidal, acaricidal, and anthelminthic agents known. Avermectins have been shown to be toxic to most insects although potency and speed of action can vary widely (Strong and Brown, 1987). These compounds are used commercially to control pests in the orders Isoptera, Blattodea, Phthiraptera, Thysanoptera, Coleoptera, Siphonaptera, Diptera, Lepidoptera, and Hymenoptera. Abamectin, the compound most widely used for insect control, has been shown to be a potent stomach toxin in cockroaches (Cochran, 1985; Rust, 1986; Koehler *et al.*, 1991), fire ants (Glancey *et al.*, 1982), Argentine ants (Baker *et al.*, 1985), vespid wasps (Chang, 1988), termites (Su *et al.*, 1987), various blood-feeding Diptera (Miller *et al.*, 1986; Allingham *et al.*, 1994), and sheep-biting lice, *Bovicola ovis* (Rugg and Thompson, 1993). Among agricultural pests, the compound is highly toxic to tobacco hornworm (*Manduca sexta*), diamondback moth (*Plutella xylostella*), tomato pinworm (*Keiferia lycopersicella*), tobacco budworm (*H. virescens*), Colorado potato beetle (*L. decemlineata*), and the serpentine leafminer (*L. trifolii*) (lethal concentration (LC_{90}) values range between 0.009 and 0.19 $\mu g\,ml^{-1}$). However, it is less potent against certain Homoptera and most Lepidoptera (LC_{90} values range between 1 and >25 $\mu g\,ml^{-1}$) (Dybas, 1989; Lasota and Dybas, 1991; Jansson and Dybas, 1998). Although abamectin is toxic to certain aphids (e.g., LC_{90} values against black bean aphid, *Aphis fabae* and cotton aphid, *Aphis gossypii* range from 0.4 to 1.5 $\mu g\,ml^{-1}$) (Putter *et al.*, 1981; Dybas and Green, 1984), it was not as effective at controlling aphids in translaminar assays (Wright *et al.*, 1985). The reduced efficacy at controlling aphids is probably due to its prime activity as a stomach poison and its reduced concentrations in phloem tissue, where aphids actively feed. Poor residual control of aphids in the field has been confirmed in several studies (Dybas, 1989 and references therein).

Emamectin benzoate is a recently introduced avermectin that is highly potent to a broad spectrum of lepidopterous pests (Jansson and Dybas, 1998). LC_{90} values for emamectin benzoate against a variety of lepidopterous pests range between 0.002 and 0.89 $\mu g\,ml^{-1}$ (Dybas, 1989; Cox *et al.*, 1995b; Jansson and Dybas, 1998). The hydrochloride salt of emamectin was up to 1500-fold more potent against armyworm species, e.g., beet armyworm (*Spodoptera exigua*), than abamectin (Trumble *et al.*, 1987; Dybas *et al.*, 1989; Mrozik *et al.*, 1989). Emamectin hydrochloride was also 1720-, 884-, and 268-fold more potent to *S. eridania* than methomyl, thiodicarb, and fenvalerate, respectively, and 105- and 43-fold more toxic to cotton bollworm (*H. zea*) and tobacco budworm (*H. virescens*) larvae than abamectin (Dybas and Babu, 1988). Recent studies showed that emamectin benzoate was 875- to 2975-fold and 250- to 1300-fold more potent than tebufenozide to *H. virescens* and *S. exigua,* respectively. Emamectin benzoate was also 12.5- to 20-fold and 250- to 500-fold more potent than λ-cyhalothrin and 175- to 400-fold and 2033- to 8600-fold more potent than fenvalerate to these two Lepidoptera, respectively (Jansson *et al.*, 1998). Emamectin benzoate was 1.2- to 4.8-orders of magnitude more potent to lepidopterous pests of cole crops (e.g., *S. exigua, P. xylostella*, and cabbage looper, *Trichoplusia ni*), than other new insecticides, including chlorfenapyr, fipronil, and tebufenozide (Jansson and Dybas, 1998; Argentine *et al.*, 2002b).

Emamectin benzoate is markedly less toxic to most nonlepidopteran arthropods. Emamectin is 8- to 15-fold less toxic to the serpentine leafminer, *L. trifolii* and the two-spotted spider mite, *T. urticae,* respectively, than abamectin (Dybas *et al.,* 1989; Cox *et al.*, 1995a). Emamectin benzoate and abamectin are comparable in their potency against Mexican bean beetle, *Epilachna varivestis*, and Colorado potato beetle, *L. decemlineata* (Dybas, 1989). Emamectin benzoate is markedly less toxic to black bean aphid, *A. fabae*, than abamectin (Jansson and Dybas, 1998).

The macrocyclic lactones are widely used in animal health applications. The use of these compounds for antiparasitic therapy has been recently reviewed (Raymond and Sattelle, 2002; Vercruysse and Rew, 2002a). James *et al.* (1980) demonstrated the initial insecticidal activity of crude extracts and partially purified avermectins against Australian sheep blowfly, *L. cuprina*. Hughes and Levot (1990) examined the potencies of abamectin, ivermectin, and 4-deoxy-4-epi(methyl amino) avermectin B_1 in *in vitro*

assays with *L. cuprina*. All three avermectins were equally potent against newly hatched larvae, and an order of magnitude more potent than diazinon when it was first introduced for blowfly control. Similarly, ivermectin is about two orders of magnitude more potent than deltamethrin against pyrethroid-susceptible larvae of *L. cuprina* (Rugg *et al.*, 1995a). Ostlind *et al.* (1997) determined that ivermectin and emamectin were more potent than a number of common insecticides in a bioassay using larvae of *Lucilia sericata*. However, these workers found that abamectin was about 100-fold less toxic than ivermectin.

Avermectins have similar potency against most myiasis producing dipterans. Abamectin or ivermectin concentrations of 5–20 ng ml^{-1} in rearing medium were toxic to early stage larvae of *Cochliomia macellaria* (Chamberlain, 1982) and *Chrysomya bezziana* (Spradbery *et al.*, 1985). Similarly, avermectins are highly potent against parasitic larvae in the families Cuterebridae (Ostlind *et al.*, 1979; Roncalli, 1984), Gasterophilidae (Klei and Torbert, 1980; Craig and Kunde, 1981) and Oestridae (Preston, 1982; Yazwinski *et al.*, 1983).

Avermectins are also potent against hematophagous dipterans. Miller *et al.* (1986) demonstrated that the therapeutic anthelminthic (subcutaneous) dose of ivermectin would be effective against the blood-feeding horn fly, *Haematobia irritans*, for more than 2 weeks. Standfast *et al.* (1984) found that this same dose in cattle produced 99% mortality in engorged ceratopogonid midges 48 h after feeding for up to 10 days after treatment. *In vitro* studies have demonstrated that the subcutaneous dose of ivermectin in cattle kills 98% of buffalo flies fed for 7 days on blood taken 1 day after treatment (Kerlin and East, 1992). *In vitro* blood-feeding assays demonstrate that ivermectin is highly toxic to horn fly (88 h LC_{50} was 3–7 ng ml^{-1}) (Miller *et al.*, 1986) and buffalo fly (*H. irritans exigua*) (48 h LC_{50} was 30–60 ng ml^{-1}) (Allingham *et al.*, 1994). Adult tsetse fly (Langley and Roe, 1984), stable fly (*Stomoxys calcitrans*) (Miller *et al.*, 1986), and mosquitoes (Pampiglione *et al.*, 1985) tend to be less susceptible and generally survive feeding on animals treated at therapeutic dose rates.

Fleas are generally considered to be relatively insensitive to avermectins or milbemycins systemically administered at, or slightly above, doses that provide ectoparasite control in production animals (Strong and Brown, 1987; Zakson-Aiken *et al.*, 2001). However, Zakson-Aiken *et al.* (2001) examined a milbemycin and 19 avermectin aglycones, monosaccharides, and disaccharides for toxicity to fleas in an artificial membrane feeding system and found that 19 of these compounds produced between 52% and 97% mortality in fleas fed a dose of 20 μg ml^{-1}. The potencies of these compounds, which included abamectin, selamectin, ivermectin, and milbemycin D, were remarkably similar, yet the most potent compound was inactive when tested at 1 mg kg^{-1} subcutaneously in the dog (Zakson-Aiken *et al.*, 2001). By contrast, selamectin provides effective flea control for up to 4 weeks after topical application at 6 mg kg^{-1} on dogs (Banks *et al.*, 2000; Bishop *et al.*, 2000).

Sucking lice on cattle are effectively controlled by therapeutic doses of avermectins, but biting lice are rarely affected by oral or injectable doses (Benz *et al.*, 1989). However, topical administration to cattle does give effective control of biting lice (Benz *et al.*, 1989). *In vitro* studies with sheep biting lice indicate that efficacy is not due to direct contact activity, but rather to the differential distribution following application resulting in the availability of a toxic oral dose. Rugg and Thompson (1993) examined the toxicity of abamectin, ivermectin, and cypermethrin to the sheep-biting, louse *Damalinia ovis*. These workers found that avermectins were an order of magnitude less potent than cypermethrin when assessed in a contact bioassay. However, in an assay incorporating ingestion and contact action both macrocyclic lactones were an order of magnitude more potent than cypermethrin.

Macrocyclic lactones are also highly toxic to many dung-feeding insects, but toxicity may vary widely between life stages. Dung-feeding Diptera and Coleoptera are highly susceptible; however, adult dung beetles are relatively insensitive. Rugg (1995) found that adult *Onthophagus gazella* were four orders of magnitude less susceptible to ivermectin or moxidectin than larvae in *in vitro* bioassays. This relative insensitivity in adult dung beetles with no significant effects on adult mortality seen in mature beetles fed dung from cattle treated with ivermectin has been reported previously (Ridsdill-Smith, 1988; Wardhaugh and Rodriguez-Mendez, 1988; Fincher, 1992). However, newly emerged and immature adult beetles may be affected negatively by ivermectin residues (Wardhaugh and Rodriguez-Mendez, 1988; Houlding *et al.*, 1991). Adult dung beetles are sexually immature at emergence and have an initial period of intense feeding. It is during this period that they would be most susceptible to residues in feces. Nevertheless, the relative insensitivity of adult dung beetles is attributable to ingestion being the main route of toxicity, to the feeding behavior of the beetles, and the characteristics of the compounds. Adult dung beetles ingest only the liquid and colloidal constituents of dung,

as their mouthparts are unsuitable for solids (Bornemissza, 1970). Avermectins and similar compounds bind tightly to soil and organics, and are virtually insoluble in water (Halley *et al.*, 1989b) and could be expected to partition differentially to the solid components of dung. Thus, adults would be expected to ingest relatively low concentrations of these compounds when feeding on the liquid portion of dung.

Milbemycins generally tend to have lower toxicities to insects than the avermectins, but similar or higher potencies against some nematodes and acarids (McKellar and Benchaoui, 1996). *In vitro* bioassays have shown that moxidectin is 50- to 100-fold less toxic than ivermectin and abamectin to the sheep blowfly, *L. cuprina*, and about sixfold less potent than these two avermectins against sheep-biting lice (Rugg, 1995). This difference is clearly demonstrated in the effects of these compounds on dung feeding insects. An *in vitro* comparison of moxidectin and abamectin (Doherty *et al.*, 1994) found that abamectin was about 50-fold more toxic to larvae of a dung beetle (*O. gazella*) and buffalo fly than moxidectin when added to cattle feces. Rugg (1995) observed a similar result with both ivermectin and abamectin, which were at least an order of magnitude more potent than moxidectin to adults and larvae of a dung beetle and larvae of a dung-feeding fly (*T. brevicornis*). While ivermectin residues are generally considered to be toxic to some dung beetle larvae and fly larvae for up to 4 weeks after the treatment of cattle, there are differing reports for moxidectin. Strong and Wall (1994) found that moxidectin residues had no toxic effects on the larvae of beetles and cyclorrhaphous flies in cattle dung, and similarly, Fincher and Wang (1992) concluded that dung from moxidectin treated animals did not affect two species of dung beetles. However, Webb *et al.* (1991) reported that feces from cattle treated with a low, controlled-release dose of moxidectin were toxic to larvae of the face fly, *Musca autumnalis*, and concluded that the therapeutic injectable dose of moxidectin would be an effective control of *M. autumnalis* larvae in dung. Miller *et al.* (1994) reported significant mortality in horn fly larvae in dung for up to 28 days after oral or injectable treatment of cattle with moxidectin. Rank ordering of the negative effects of various avermectins and moxidectin on insect development in the dung of treated cattle was doramectin $>$ivermectin $\geq$ eprinomectin $\gg$ moxidectin (Floate *et al.*, 2001, 2002).

While moxidectin is generally less potent against insects than the avermectins in *in vitro* evaluations, it is commonly used at the same or similar therapeutic dose rates in production animals. Interestingly, the spectrum of insects controlled by these products is remarkably similar (Shoop *et al.*, 1995; McKellar and Benchaoui, 1996). The only macrocyclic lactones that have been specifically developed for primary insect control on animals are avermectins: ivermectin for blowfly and lice control on sheep (Eagleson *et al.*, 1993a, 1993b; Rugg *et al.*, 1993, 1995a, 1995b; Thompson *et al.*, 1994), and selamectin for flea control on cats and dogs (Benchaoui *et al.*, 2000; McTier *et al.*, 2000a, 2000b).

5.2.4.1.2. Acarids, copepods, and helminths Macrocyclic lactones are highly potent acaricides. Abamectin and natural milbemycins are widely used as agricultural miticides. Abamectin is highly effective against a broad spectrum of phytophagous mites and is one of the most potent acaricides with LC_{90} values ranging between 0.02 and 0.24 $\mu g\,ml^{-1}$ for mites in the families Tetranychidae, Eriophyidae, and Tarsonemidae (Lasota and Dybas, 1991). Eriophyid mites, such as the citrus rust mite, *Phyllocoptruta oleivora*, and various tetranychid mites, such as *T. urticae*, are among the most susceptible (Dybas, 1989). Other phytophagous mites, such as citrus red mite, *Panonychus citri* (LC_{90} = 0.24 $\mu g\,ml^{-1}$) are slightly more tolerant (Dybas, 1989). Similarly, ticks and parasitic mites are variably susceptible to the macrocyclic lactones. Much of the variation in potency against ticks relates to the different life cycle of ticks, the relatively slow action of these compounds against ticks, and the interactions with bioavailability of the compound in the host. These compounds tend to be much more effective against single host ticks; and are often considered relatively poor compounds against multihost ticks (McKellar and Benchaoui, 1996). In multihost ticks, adults are the infestive stage and are the least sensitive to macrocyclic lactones. Parasitic mites show similar variation: the deep burrowing sarcoptic mange mites that feed directly on blood and body fluids are highly sensitive, while chorioptic mange mites that live and feed on the superficial dermal surface are relatively insensitive (Benz *et al.*, 1989).

Macrocyclic lactones are also toxic to a number of parasitic copepods and ivermectin, emamectin benzoate, and doramectin have been used for control of parasitic sea lice in farmed salmon (Burka *et al.*, 1997; Davies and Rodger, 2000; Roth, 2000).

The macrocyclic lactones are highly potent nematicides, but have no useful activity against trematodes or cestodes. These compounds are especially toxic to the microfilarial stages of many filaroid nematodes (McKellar and Benchaoui, 1996). This extreme potency against microfilaria is best

demonstrated in the use of these compounds for heartworm control in dogs. Oral doses of 3–12 $\mu g\,kg^{-1}$ of moxidectin or ivermectin once a month provide effective protection against heartworm infection in dogs (Guerrero *et al.*, 2002). The oral use rate of these compounds for general nematode control in ruminants is about 200 $\mu g\,kg^{-1}$ (McKellar and Benchaoui, 1996).

5.2.4.2. Bioavailability

5.2.4.2.1. Crop protection uses Macrocyclic lactones are very susceptible to rapid photodegradation. The half-life of abamectin as a thin film under artificial light or simulated sunlight was 4–6 h and the rate of degradation of abamectin on petri dishes and on leaves was markedly greater in light than in dark environments (MacConnell *et al.*, 1989). The half-life of emamectin benzoate has been estimated to be 0.66 days on celery (Feely *et al.*, 1992) and is expected to be even shorter on cole crops. Photoirradiation of avermectins leads to the production a large number of decomposition products (Mrozik *et al.*, 1988), and a number of these photodegradates have also been identified for abamectin (Crouch *et al.*, 1991) and emamectin benzoate (Feely *et al.*, 1992). Many of these photodegradates show impressive insecticidal activity against larval lepidopterans (Argentine *et al.*, 2002a).

Despite the rapid degradation of avermectin insecticides in sunlight, significant amounts of these compounds are taken up rapidly via translaminar movement into sprayed foliage (Wright *et al.*, 1985; Dybas, 1989 and references therein). When abamectin was applied to plants held in the dark, the prolonged stability resulted in greater penetrability into leaves and more effective mite control (MacConnell *et al.*, 1989). Wright *et al.* (1985) demonstrated that this translaminar movement of abamectin produced good control of mites, but aphids were not controlled. They surmised that abamectin residues were probably abundant in the parenchyma tissues of leaves where mites feed, whereas abamectin probably did not distribute into the phloem tissue where aphids feed. The excellent residual efficacy of abamectin against several dipteran and lepidopteran leafminers is probably also due to translaminar movement and the presence of abamectin reservoirs in parenchyma tissue (Jansson and Dybas, 1998). This lack of true systemic activity (distribution into the phloem) in plants following spray application is demonstrated by the lack of residual efficacy against aphids. Spray applications of abamectin that had good contact efficacy provided little if any residual control of the aphids *Myzus persicae* (Johnson, 1985) and *A. fabae* (Green and Dybas, 1984). Similarly, the lack of downward transport of abamectin sprayed on foliage results in poor control of root knot nematodes (Stretton *et al.*, 1987; Cayrol *et al.*, 1993). By contrast, root dip, soil application or stem injections of avermectins have shown the potential to provide effective control of these parasites (Sasser *et al.*, 1982; Jansson and Rabatin, 1997, 1998).

5.2.4.2.2. Animal health uses In animal health, the high potency and lipophilic nature of the macrocyclic lactones allows extensive systemic delivery through a variety of routes. These compounds are used in oral, injectable, and topical formulations. The route of delivery, however, influences the bioavailability and distribution of the compounds in the host animal and thus the efficacy against different target parasites. Similarly, bioavailability can vary dramatically between species and be markedly affected by feed quantity (Ali and Hennessy, 1996) or composition (Taylor *et al.*, 1992) when orally administered. Efficacy against parasites may be dependent on transport in the plasma and distribution to vascular or nonvascular sites that constitute the parasite habitat. The pharmacokinetics of the macrocyclic lactones were reviewed by Hennessy and Alvinerie (2002).

Following most means of administration, macrocyclic lactones are eliminated fairly rapidly from the treated animals; elimination half-lives in various species range from about 3 to 10 days (see Hennessy and Alvinerie, 2002). Regardless of the means of administration or the species treated, the main route of elimination of the compounds is via feces with the compounds passing into the gastrointestinal tract in the bile (Hennessy and Alvinerie, 2002). A number of controlled release devices (Shoop and Soll, 2002) or sustained release formulations (Rock *et al.*, 2002; Shoop and Soll, 2002) using macrocyclic lactones have been used to provide long-term protection against parasites.

The most dramatic differences between application methods are seen with certain insect ectoparasites. While a number of blood-sucking parasites, such as sucking lice of cattle, are controlled by therapeutic doses of macrocyclic lactones administered orally or by injection, chewing lice are generally not susceptible. Topical applications (generally at about a 2.5-fold higher dose rate) are usually highly effective against chewing lice (Strong and Brown, 1987; Vercruysse and Rew, 2002b). Similar results have also been observed in lice on sheep (Coop *et al.*, 2002). While the efficacy and spectrum of these topical formulations against internal parasites is similar to the oral or injectable treatments, this

greater efficacy against chewing lice is thought to be a result of a high concentration of the active ingredient on the surface of the skin where these parasites feed (Titchener *et al*., 1994). Similarly, most of the macrocyclic lactone pour-on formulations for cattle have demonstrated a persistent efficacy against the blood-feeding horn fly and buffalo fly that is not seen with oral or injectable formulations (Vercruysse and Rew, 2002b).

This apparent greater efficacy of pour-on formulations against external parasites is presumably the result of deposition of the active compound on, and in, the skin. The high lipophilicity of the macrocyclic lactones is likely to result in the formation of depots of active ingredient in skin lipids and oil and fat secretions. This characteristic has been exploited in topical formulations of ivermectin that provide long-term residual control of blowfly and lice on sheep (Eagleson *et al*., 1993a, 1993b; Thompson *et al*., 1994), and selamectin which controls fleas on dogs and cats for at least 1 month (Benchaoui *et al*., 2000). Even greatly exaggerated oral or injectable doses of macrocyclic lactones are considered unlikely to provide residual control of fleas (Zakson-Aiken *et al*., 2001). In sheep, topically applied ivermectin is thought to bind to skin lipids and secretions and may be passively distributed around the sheep's body in this medium following application to a discrete site (Rugg and Thompson, 1997). Selamectin is thought to selectively partition into sebaceous glands of dogs and cats from where it is slowly released to the skin over an extended period (Hennessy and Alvinerie, 2002).

5.2.4.3. Safety and Selectivity

5.2.4.3.1. Crop protection uses Abamectin is generally considered to be nonphytotoxic under normal use even in sensitive ornamental plants (Wislocki *et al*., 1989), although mild foliar spotting has been noted in some ferns, daisies, and carnations (Dybas, 1989). Phytotoxicity was not affected by the addition of spray oils (Green *et al*., 1985), although, the addition of spray oils to abamectin has produced epidermal damage in pears that is not seen with the use of abamectin alone (Hilton *et al*., 1992).

Integrated pest management (IPM) involves the use of all available means (chemical, biological, cultural, physical, etc.) to achieve effective control of pests or pest damage. Central to the design of IPM programs are selective insecticides that reduce pest abundance and yet are innocuous to beneficial predators or parasites by allowing their survival and range expansion. The suitability of pesticides for use in IPM programs is based on the differential toxicity of a compound to pest and beneficial arthropod populations. Differential toxicity can occur through pharmacokinetic or metabolic differences between pests and beneficial organisms (physiological selectivity) or by a compound's unique qualities that result in toxic exposure of phytophagous pests with concomitant reduced exposure of beneficial organisms (ecological selectivity). The macrocyclic lactone insecticides possess both of these qualities, thereby making them highly selective and compatible with IPM.

The ecological selectivity of the avermectins and milbemycins results from a number of qualities of these compounds following application in the field. As noted earlier, avermectin insecticides are readily taken up by plant foliage. Foliar uptake via translaminar movement results in a reservoir of the toxicant inside the leaf (MacConnell *et al*., 1989). Any remaining compound on the outside of foliage is rapidly degraded by sunlight, thereby resulting in minimal residues of the compound on the plant surface soon after application. These qualities of the avermectin insecticides that result in the selective availability of the compounds to phytophagous pests and reduced exposure to nonphytophagous organisms are the main reasons for their compatibility with beneficial arthropods and IPM programs.

A number of researchers have shown that applications of abamectin did not disrupt the *Liriomyza* leafminer–parasitoid complex on a variety of vegetable crops (see Dybas, 1989). Trumble and Alvarado Rodriguez (1993) demonstrated that because of the reduced toxicity of abamectin to natural enemies, it was an important component of a multiple-pest IPM program on fresh market tomato that was based on intensive sampling, parasitoid releases, mating disruption, microbial pesticides, and abamectin. Abamectin has also been shown to be less detrimental to certain life stages of two leafminer parasitoids, *Diglyphus intermedius* and *Neochrysocharis punctiventris*, compared with other commonly used insecticides (Schuster, 1994).

The differential toxicity of abamectin to a variety of pest and predatory mite species is also well documented (see Lasota and Dybas, 1991). Hoy and Cave (1985) showed that although abamectin was toxic to the predator *Metaseiulus occidentalis*, it was more toxic to the two-spotted spider mite, *T. urticae*. Similar results have been found with other predatory mite species (Grafton-Cardwell and Hoy, 1983; Zhang and Sanderson, 1990). Hoy and Cave (1985) also showed that 2–4 day field-aged residues of abamectin were safe for *M. occidentalis*. Several other studies demonstrated that abamectin was less toxic to naturally occurring

and introduced natural enemies of pest mites, and for this reason, it selectively kills target pests and conserves their natural enemies (Dybas, 1989; Lasota and Dybas, 1991).

Zchorifein *et al.* (1994) found that abamectin was compatible with *Encarsia formosa*, an important component of IPM programs for greenhouse whitefly, *Trialeurodes vaporariorum*. No mortality was observed when adult parasitoids were exposed to 24 h residues of abamectin. They found that a management program based on the combined treatment of abamectin with releases of *E. formosa* maintained lower densities of the whitefly on poinsettia throughout the season and required fewer applications of abamectin compared with a management program based on applications of abamectin alone. Similarly, Brunner *et al.* (2001) found that while abamectin was highly toxic when applied topically to two parasitoids of leafrollers, 1-day-old residues were not toxic.

Like abamectin, emamectin benzoate is less toxic to beneficial arthropods such as honeybees, parasitoids, and predators. Kok *et al.* (1996) reported that emamectin hydrochloride had minimal adverse effects on two hymenopterous parasitoids (*Pteromalus puparum* and *Cotesia orobenae*) of Lepidoptera on broccoli. Contact activity of emamectin benzoate residues on alfalfa against two species of bees declined rapidly and was negligible 24 h after treatment (Chukwudebe *et al.*, 1997). They determined that bee mortality was directly related to transient dislodgeable residues and thus these beneficial insects could be expected to survive and colonize treated crops within relatively short intervals after applications of emamectin benzoate. Sechser *et al.* (2003) found that emamectin benzoate was relatively safe to a number of insect predators of sucking pests on cotton.

The selectivity of abamectin has been widely investigated in mites. Trumble and Morse (1993) showed that abamectin was compatible with *Phytoseiulus persimilis* in field-grown strawberry. They found that the highest net economic return was achieved when several releases of the predatory mite *P. persimilis* were integrated with suitably timed applications of abamectin. In a laboratory leaf-disc bioassay, adult females of the predatory mite *Amblyseius womersleyi* dipped in abamectin solution showed low mortality (16.6%), while all *T. urticae* females died within 24 h after dipping (Park *et al.*, 1996). In apple, abamectin was highly compatible with the phytoseiid mites *M. occidentalis* and *Amblyseius fallacis*. Abamectin was effective at reducing and maintaining numbers of European red mites (*Panonychus ulmi*) at or below the economic threshold for at least 3 weeks after application. Although predatory mite numbers declined initially, they quickly resurged resulting in favorable predator to prey ratios that were comparable or superior to those found in nontreated plots, and aided in mite suppression for the remainder of the growing season (Jansson and Dybas, 1998).

In glasshouse roses, Sanderson and Zhang (1995) found that full canopy applications of abamectin at 3–5 day spray intervals effectively controlled *T. urticae* populations, but were detrimental to the predatory mite *P. persimilis*. However, by applying abamectin to the upper canopy of plants only, excellent mite control in the marketable portion of the plant was achieved and predatory mite populations in the lower canopy were conserved. This demonstrated the potential for integrating abamectin with natural predators for control of a target pest, even under intense abamectin pressure.

5.2.4.3.2. Animal health uses The macrocyclic lactones are generally considered to be relatively safe in mammals. Glutamate-gated chloride channels have not been reported in mammals. Clinical signs are associated with neurotoxicity of the central nervous system as this is the site of GABA-gated chloride channels in mammals. The poor distribution of these compounds through the blood–brain barrier and/or their rapid removal by the transmembrane protein, P-glycoprotein, are thought be responsible for their lack of toxicity to mammals (Shoop and Soll, 2002; Abu-Qare *et al.*, 2003). Increased susceptibility to avermectins has been observed in Murray Grey cattle (Seaman *et al.*, 1987) and in some collie-breed dogs (Paul *et al.*, 1987). It is thought that a deficiency of P-glycoprotein in these animals results in increased accumulation of avermectins in the central nervous system and the resultant neurotoxicity (Shoop and Soll, 2002; Roulet *et al.*, 2003).

In animal health, nontarget effects of macrocyclic lactones are generally minimized due to their main use as systemic parasiticides. The compounds are applied discretely to the target host and not released into the environment. The major nontarget effects in animal health uses are on the insect fauna of dung of treated animals. Regardless of the route of administration, the major means of elimination of these compounds from animals is via the feces and the major component in feces is usually the parent compound (Campbell *et al.*, 1983; Chiu and Lu, 1989). Feed-through compounds for the control of pestiferous Diptera in dung have been in use, especially in cattle, for many years, yet little attention has been paid to the effects on nontarget dung

fauna (Strong, 1992). Similarly, most of the compounds used as external parasiticides for cattle are toxic to dung insects, but organophosphorus and pyrethroid compounds are more toxic to dung-inhabiting insects than avermectins (Bianchin *et al.*, 1992). However, there has been a great deal of attention given to possible environmental consequences of systemic parasiticides, especially avermectins and related compounds, with entire journal volumes (e.g., *Veterinary Parasitology* 48, 1993) and dedicated regulatory or scientific workshops (National Registration Authority, 1998; Alexander and Wardhaugh, 2001) devoted to this subject.

This rise in interest is probably related to the widespread use of these compounds. Their broad spectrum, encompassing both nematodes and arthropods, has resulted in their extensive use, and especially where gastrointestinal worms are the prime target, most arthropods could be considered nontarget organisms. Certainly, in countries where the introduction of dung beetles to control dung build-up and dung breeding pests have occurred, any compounds with adverse effects on these beneficial agents will gain some attention. Also, the differing toxicities of related compounds marketed by different companies may be perceived as providing a commercial advantage. Hence, authors have reported the effects of ivermectin in controlling dung-breeding pestiferous Diptera (e.g., Meyer *et al.*, 1980; Miller *et al.*, 1981; Marley *et al.*, 1993), or its toxicity to dung beetles (e.g., Ridsdill-Smith, 1988; Sommer and Overgaard Nielsen, 1992; Sommer *et al.*, 1992, 1993), and that dung degradation may be retarded (e.g., Wall and Strong, 1987; Sommer *et al.*, 1992) or not affected (e.g., Jacobs *et al.*, 1988; McKeand *et al.*, 1988; Wratten *et al.*, 1993). Other reports have appeared directly comparing the effects of avermectins and moxidectin on dung fauna (Fincher and Wang, 1992; Doherty *et al.*, 1994; Floate *et al.*, 2001, 2002).

There is little doubt that avermectins and related compounds have the potential to affect dung-inhabiting insects. Moxidectin has little if any impact on dung insects, but also is less efficacious against pestiferous fly larvae. The selection of these compounds for certain animal health uses should be evaluated on the basis of their efficacy against pest target and on concomitant environmental concerns. Thus, for example, ivermectin use in a controlled-release device for sheep provides added protection against breech strike (Rugg *et al.*, 1998a), and residues in dung likely reduce populations of the adult blowfly population (Cook, 1991, 1993), while exerting little impact on the rate of degradation of sheep dung where insects play a relatively minor role (Cook, 1993; King, 1993). Where there are concerns over possible adverse effects of treatment for gastrointestinal worm infestation on cattle dung fauna, moxidectin would be the compound of choice (Strong and Wall, 1994). If control of arthropod ectoparasites or their dung-feeding stages is of importance (Marley *et al.*, 1993), an avermectin may be preferred because of its greater toxicity to insects. Even so, a study examining the effects of commercial ivermectin use in cattle in South Africa (Scholtz and Krüger, 1995) found that dung insect populations recovered rapidly following an initial depression. They concluded that the long-term effects on dung fauna might not be as severe as previous studies have claimed. However, simulation of the impact of eprinomectin on dung beetle populations using computer modeling suggests that, in the absence of immigration, a single treatment of eprinomectin could reduce beetle activity by 25–35% in the next generation (Wardhaugh *et al.*, 2001). In studies directly comparing the effects of macrocyclic lactones in cattle dung, avermectins result in lethal and sublethal effects on dung fauna in feces excreted for a number of weeks after treatment, while moxidectin residues are relatively innocuous (Fincher and Wang, 1992; Doherty *et al.*, 1994; Floate *et al.*, 2001, 2002; Wardhaugh *et al.*, 2001).

5.2.5. Uses

5.2.5.1. Crop Protection

Abamectin is registered worldwide for control of mites and certain insect pests on a variety of ornamental and horticultural crops and on cotton. Abamectin is effective for controlling agromyzid leafminers, *Liriomyza* spp., Colorado potato beetle, *L. decemlineata*, diamond back moth, *P. xylostella*, tomato pinworm, *K. lycopersicella*, citrus leafminer, *Phyllocnistis citrella*, and pear psylla, *Cacopsylla pyricola*. Abamectin has also been incorporated into bait to control red imported fire ants and cockroaches. These and other urban pest applications were reviewed by Lasota and Dybas (1991).

Recent studies have shown that avermectins have potential as a component in Africanized honeybee abatement programs (Danka *et al.*, 1994). Another novel use is the injection of abamectin into trees which controls certain phytophagous arthropods, such as elm leaf beetle (*Pyrrhalta luteola*), for up to 83 days after application (Harrell and Pierce, 1994). The main commercial agricultural use of macrocyclic lactones is as acaricides. These compounds have demonstrated mite control and residual activity superior to most acaricides on a variety of ornamental crops, food crops, and cotton (Putter

et al., 1981; Dybas and Green, 1984; Dybas, 1989). Macrocyclic lactones are also highly effective for the control of plant parasitic nematodes following injection application (Jansson and Rabbatin, 1997, 1998; Takai *et al.*, 2003) or soil incorporation (Blackburn *et al.*, 1996). Emamectin benzoate, milbemectin, and nemadectin are used commercially for the control of pine wilt nematode in Japan.

Emamectin benzoate is used for broad-spectrum control of lepidopteran pests on certain vegetable crops. This compound is very effective against numerous lepidopteran pests of a variety of crops. It is expected that the compound will be used to control lepidopterous pests on a wide variety of vegetable, tree, and row crops and also for control of thrips on eggplant and tea in Japan (Jansson and Rabatin, 1997).

5.2.5.2. Animal and Human Health

The macrocyclic lactones have had a dramatic impact on animal health. Their potency and broad spectrum has resulted in this chemistry dominating the parasiticide market. Macrocyclic lactones have been commercialized for the control of nematodes and arthropod parasites for most common food-producing and companion animals and are widely used "off-label" for parasite control in many other species. Avermectins (e.g., emamectin) are also used for control of copepod parasites of farmed salmon (Davies and Rodger, 2000). In human health, ivermectin has been used since 1987 in a compassionate program in Africa and Central and South America to control *Onchocerca volvulus* which is the causative agent of river blindness in man (Shoop and Soll, 2002). The program was expanded recently to include the reduction of spread of elephantiasis caused by lymphatic filarid nematodes. Recently, moxidectin has been demonstrated to be safe and well tolerated in humans (Cotreau *et al.*, 2003). Moxidectin is more efficacious than ivermectin in *Onchocerca* models and is currently undergoing clinical trials prior to inclusion in filarid control programs (Molyneux *et al.*, 2003). Ivermectin has been approved for treatment of intestinal strongiloidosis scabies in humans, and is also useful for the treatment of louse infestations (Elgart and Meinking, 2003). These authors consider that there may be a number of additional uses for the macrocyclic lactones as antiparasitic medications for parasites of skin in humans.

5.2.6. Resistance

5.2.6.1. Insects

Resistance to the avermectins in insects has been reviewed by Clark *et al.* (1995). In general, a variety of biochemical and pharmacokinetic mechanisms may contribute to avermectin resistance in arthropods, although biochemical mechanisms tend to be more important among most arthropod systems studied to date. However, there are many conflicting reports on the importance of different resistance mechanisms. Similarly, cross resistance between avermectin insecticides/acaricides and other classes of chemistry is not well understood, and there are probably equal numbers of reports demonstrating cross-resistance as there are those refuting it.

Cross-resistance between abamectin and pyrethroids has been reported for field strains of houseflies (Scott, 1989; Geden *et al.*, 1990). Abro *et al.* (1988) proposed that there was a low level of cross resistance to abamectin in a field strain of diamondback moth that was highly resistant to DDT, malathion, and cypermethrin when assessed in a topical assay. However, the same population was equally susceptible to abamectin as the baseline colony in an ingestion bioassay. Roush and Wright (1986) found no evidence of cross-resistance to avermectins in houseflies resistant to diazinon, dieldrin, DDT, or permethrin, and Parella (1983) reported no cross-resistance to avermectins in a pyrethroid-resistant agromyzid fly. Campanhola and Plapp (1989) determined that there was no cross-resistance to abamectin in pyrethroid-resistant tobacco budworm, where both target site resistance and metabolic resistance to pyrethroids were present. Similarly, Cochran (1990) concluded that pyrethroid-resistant field populations of German cockroach were not cross-resistant to abamectin. Argentine and Clark (1990) examined a susceptible laboratory strain and a multiple-resistant field strain of Colorado potato beetle, and found no difference in their dose responses to abamectin. No cross-resistance to abamectin was observed in a laboratory-selected pyrethroid-resistant strain of citrus thrip, although cross-resistance was detected to DDT and some organophosphates and carbamates (Immaraju and Morse, 1990). Rugg and Thompson (1993) reported that pyrethroid-resistant sheep biting lice (*B. ovis*) were not cross-resistant to ivermectin.

Beeman and Stuart (1990) examined a number of pesticides against a field-collected strain of red flour beetle (*Tribolium castaneum*) resistant to lindane that had been further selected with dieldrin in the laboratory. These workers found cross-resistance to other cyclodienes, but not to abamectin nor to organophosphates. Resistance to cyclodienes, accounted for by channel mutants in the Rdl GABA-gated chloride channel subunit (review: ffrench-Constant, 1994), usually extends to all insecticides that block chloride ion channels, and this resistance is not

conferred to avermectins as these activate chloride channels and therefore act at a separate site (Bloomquist, 1993). Rohrer *et al.* (1995) showed that fipronil, which interacts with GABA-gated chloride channels (as an antagonist) did not affect ivermectin binding either in *Drosophila* head membranes or in locust neuronal membranes.

Ismail and Wright (1991) examined the toxicities of a number of insect growth regulators, and abamectin, to a susceptible strain of diamondback moth and to strains selected for resistance to the growth regulators chlorfluazuron and teflubenzuron. They found that cross-resistance to other growth regulators was variable and did not detect cross-resistance to abamectin. Recently, Zhao *et al.* (2002) showed that the resistance to spinosad in a field population of diamondback moth was not cross-resistant to emamectin benzoate.

Scott (1989) proposed that cross-resistance to abamectin in pyrethroid-resistant houseflies was polygenic and due to decreased cuticular penetration and enhanced metabolism mediated by mixed-function oxidases. Subsequently, Scott *et al.* (1991) reported laboratory selection of high-level abamectin resistance in these field-collected houseflies; after seven selections resistance ratios of >60 000-fold (determined by topical application) and 36-fold (determined by residual exposure) were reached. In their study the synergists piperonyl butoxide, diethyl maleate, and *S*,*S*,*S*-tributylphosphorotrithioate did not affect the toxicity of abamectin, indicating that resistance was not due to enhanced metabolism mediated by mixed function oxidases, glutathione transferases, or hydrolases. Konno and Scott (1991) found that resistance in this selected strain resulted from decreased cuticular penetration (>1700-fold) and altered abamectin binding (35-fold). This strain was also cross-resistant to two abamectin analogs and resistance was highly recessive.

Laboratory selection of abamectin against two strains of Colorado potato beetle resulted in resistance levels of 21-fold for a mutagen-induced resistance and 38-fold by direct selection. Both resistance factors were incompletely dominant and polyfactorial (Argentine and Clark, 1990). Oxidative metabolism and possibly carboxylesterase activity were responsible, in part, for resistance to abamectin (Argentine, 1991; Argentine *et al*., 1992). Lamine (1994) found that abamectin-resistant larvae of *L. decemlineata* were seven- to tenfold less susceptible to emamectin benzoate than the baseline colony in a topical bioassay. No cross-resistance between abamectin and emamectin benzoate was evident in adult beetles. Recent studies showed that *L. decemlineata* populations which were 15- to 23-fold less sensitive to abamectin in a contact, topical bioassay (Clark *et al*., 1995) were classified as susceptible to abamectin in a diet-based ingestion assay (Dively and Jansson, 1996). Recently, oxidative metabolism was confirmed as a principal resistance mechanism in laboratory-selected, abamectin-resistant Colorado potato beetle (Yoon *et al*., 2002; Gouamene-Lamine *et al*., 2003).

Hughes and Levot (1990) reported that a laboratory-selected strain of *L. cuprina* resistant to organophosphates and carbamates exhibited a low level cross-resistance (two- to threefold) to abamectin and ivermectin when compared to susceptible flies. However, emamectin benzoate was equally toxic to both strains. This strain also exhibited a low level of cross-resistance to pyrethroids (Sales *et al*., 1989). A laboratory-selected pyrethroid-resistant strain of *L. cuprina* that showed cross-resistance between an organophosphate and a carbamate insecticide (Sales *et al*., 1989) was subsequently selected with deltamethrin, diflubenzuron, and butacarb resulting in levels of resistance in excess of 1000-fold to all three compounds (Kotze and Sales, 1994). These workers also found that metabolic inhibitors significantly synergized the three selected strains, indicating the involvement of both monooxygenases (mixed-function oxidases) and esterases in these resistances. Rugg *et al.* (1995a) showed that the same pyrethroid- and carbamate-resistant laboratory strain of *L. cuprina* was not cross-resistant to ivermectin. Organophosphate-resistant field strains of *L. cuprina* have also been shown to have no cross-resistance to avermectins (Hughes and Levot, 1990; Rugg *et al*., 1998b).

Rugg *et al.* (1998b) selected larvae of *L. cuprina* with ivermectin for over 60 generations and achieved an eightfold increase in tolerance compared to the parental strain. This low-level resistance reverted rapidly in the absence of selection pressure, and although enzymatic metabolism was implicated, no specific resistance mechanisms were determined. Kotze (1995) found that the induction of monooxygenase and glutathione transferase enzymes with phenobarbital in insecticide-susceptible *L. cuprina* larvae resulted in increased tolerance to butacarb, diazinon, and diflubenzuron. In similar experiments, Rugg *et al.* (1998a) found no increase in tolerance to ivermectin in induced flies that had reduced susceptibility to diazinon.

Resistant field populations of *P. xylostella* from Malaysia were not cross-resistant to *Bacillus thuringiensis* (Iqbal *et al*., 1996). Lasota *et al.* (1996) showed that there was no cross-resistance between abamectin, emamectin benzoate, permethrin, and

methomyl in *P. xylostella* using an ingestion bioassay. Following laboratory selection of a field population of *P. xylostella* from China, testing of F_1 progeny from reciprocal crosses between abamectin-resistant and abamectin-susceptible strains indicated that resistance was autosomal and incompletely recessive and backcross studies suggested that the resistance was probably controlled by more than one gene (Liang *et al.*, 2003). Further, there was little cross-resistance between abamectin and four pyrethroids (deltamethrin, β-cypermethrin, fenvalerate, and bifenthrin) and no cross-resistance between abamectin and the acylureas chlorfluazuron or flufenoxuron.

Morse and Brawner (1986) reported LC_{50} values ranging from 7 to 21 mg l^{-1} in strains of citrus thrips that had not been exposed to abamectin. Immaraju and Morse (1990) retested one of these strains that had been maintained in the laboratory and also selected for resistance to fluvalinate, and determined LC_{50} values of 0.9 and 0.4 mg ml^{-1}, respectively. Responses to abamectin in nonexposed populations varied by over 50-fold suggesting that thrips may have a large inherent variation in susceptibility to abamectin. Immaraju *et al.* (1992) reported the occurrence of two abamectin-resistant populations of western flower thrips in Californian glasshouses. Resistance ratios (LC_{90}) of 18- and 798-fold were attributed to intensive use of abamectin during the previous year (five or ten applications, respectively).

In summary, resistance to avermectins has been demonstrated in a number of insects. In all instances, although not clearly determined, resistance is believed to be polygenic, relatively slow to develop, and able to revert rapidly in the absence of selection pressure. Metabolic mechanisms seem to be the most important route of resistance in the arthropod systems studied to date, and in all cases, a number of biochemical and sometimes physiological mechanisms are implicated. Cross-resistance between avermectins and other insecticide classes is similarly ill-defined; however, it is apparent that there is little significant cross-resistance to avermectins except possibly in one strain of housefly (Scott, 1989). The variations in responses of field strains resistant to other insecticide classes to avermectins may in some cases be due to enhanced metabolism resulting from previous exposure to other insecticides, although there is evidence to both support and refute this supposition. A number of species have also demonstrated inherent population differences in response to avermectins without the influence of any predisposing factors. A wide variation among field-collected strains has been seen in several insects which does not constitute cross-resistance, nor does it indicate that this variation predisposes insects to an increased likelihood for resistance development to avermectins.

Cross-resistance between the avermectins and milbemycins (specifically abamectin, ivermectin, doramectin, and moxidectin) has been demonstrated in a number of nematode species. Because abamectin is the only avermectin compound used widely in agriculture, there have been a few studies conducted to examine cross-resistance within the class. Sensitivity to emamectin benzoate in select abamectin-resistant strains has been assessed in several insects (e.g., *L. trifolii, L. decemlineata*, *P. xylostella*) and only minimal, if any, cross-resistance has been detected (Jansson and Dybas, 1998; Jansson and Rugg, unpublished data). The reasons for the lack of cross-resistance to these closely related compounds are unclear. It is possible that the changes in the derivatization of emamectin benzoate may result in the loss or protection of the chemical bonds that are subject to enzymatic cleavage in abamectin resistance. Additionally, because macrocyclic lactones have multiple sites of action and may affect a number of different receptors to activate or potentiate chloride ion influx, subtle differences in chemistry between the different avermectins and milbemycins may alter the relative activities of compounds at the different sites. This could affect the patterns and levels of cross-resistance within the class and also be a factor in the subtle differences seen in the spectra and potencies of these compounds.

5.2.6.2. Acarids

Laboratory selection of up to 15 generations of two species of tetranychid mites with abamectin resulted in no significant increase in resistance compared with a nonselected baseline colony (Hoy and Conley, 1987). Conversely, 20 rounds of selection against a predatory phytoseiid mite resulted in a gradual and modest shift in susceptibility to abamectin (Hoy and Ouyang, 1989). A recent survey of field populations of two-spotted spider mite in California (Campos *et al.*, 1995) found that mites varied widely in their susceptibility to abamectin, with up to a 658-fold difference in susceptibility in a residual exposure assay. Levels of resistance were correlated with the amount and time of abamectin usage, and laboratory selection of a single population over 38 generations resulted in more than a 100-fold increase in resistance. Despite the higher level of resistance in a residual assay, selected mites were still considered susceptible to abamectin in a direct contact bioassay. Further, despite the wide variation in responses among field populations of mites, no field failures of the product were reported.

In *T. urticae*, resistance to abamectin has been attributed to increased excretion and decreased absorption (Clark *et al*., 1995), monooxygenases (Campos *et al*., 1996), esterases (Campos *et al*., 1996, 1997; Jansson *et al*., unpublished data), glutathione-*S*-transferases (Clark *et al*., 1995), and decreased penetration (Clark *et al*., 1995). Levels of resistance in two spotted spider mite populations collected from the field were shown to drop markedly within 2–6 weeks after collection when maintained in the absence of selection pressure (Campos *et al*., 1995; Jansson *et al*., unpublished data). Bergh *et al*. (1999) reported wide variation in susceptibility to abamectin in citrus rust mite (*P. oleivora*) field populations with no clear relationship between susceptibility and product efficacy. While some populations from commercial groves with a history of exposure to abamectin were less susceptible to abamectin, mortality was only slightly lower than that of a pristine population. Also bioassay results indicated that the responses of these field populations did not change whether they were assessed before or after abamectin spray applications.

5.2.6.3. Helminths

Ivermectin resistance was initially detected in nematodes of sheep and goats, and was generally a result of intensive use over a number of years (Shoop, 1993). Ivermectin-resistant nematodes have been shown to have cross-resistance to other avermectins and milbemycins (Shoop *et al*., 1993). However, moxidectin was significantly more toxic to many parasitic nematodes (Shoop, 1993; Shoop *et al*., 1993; Kieran, 1994) and this difference in potency has resulted in moxidectin providing economic control of ivermectin-resistant parasites in field use situations. Conder *et al*. (1993) showed that the modes of action of ivermectin and moxidectin were qualitatively similar by examining changes in membrane conductance in crab muscle fibers. These workers also demonstrated cross-resistance to moxidectin in an ivermectin-resistant strain of *H. contortus* and confirmed that moxidectin was about fourfold more potent than ivermectin against this parasite in a jird model. Recently, Ranjan *et al*. (2002) reported the results of concurrent selection of *H. contortus* for 22 generations with ivermectin and moxidectin. These workers found that worms that had developed resistance through selection with either of these macrocyclic lactones were cross-resistant to the other compound. However, the rate of development of resistance differed between the two compounds and occurred more slowly with moxidectin, which was also markedly more potent than ivermectin. See Pritchard (2002) for the most recent, detailed review of the status of resistance to macrocyclic lactones in nematodes. Briefly, resistance is still a major concern for parasites of sheep and has also been detected in some cattle parasites. Resistance has been found to be associated with enhanced P-glycoprotein expression resulting in increased efflux from the target site, but there are thought to be a number of possible resistance mechanisms including various amino acid-gated anion subunit genes, genes associated with glutamate receptors and transporters, and genes involved in amphid structure and function. The multiplicity of possible sites for macrocyclic lactone binding and activity and their variable sensitivity to different compounds may be responsible for the differential potencies seen within and between avermectins and milbemycins and suggests that products of several genes may be involved in the mechanism of action of macrocyclic lactones. Similarly, these subtle differences in the ways in which ivermectin and moxidectin act at the molecular level could result in the differences seen between these compounds in potency, rates of development of resistance, and levels of cross-resistance.

5.2.7. Summary

The macrocyclic lactones are potent insecticides, nematicides, and acaricides. The class consists of two closely related groups of compounds, the avermectins and milbemycins, which are natural fermentation products or synthetic derivatives of natural products derived from actinomycetes. The broad spectrum of activity against a variety of insects, acarids, and nematodes has led to the widespread use of these compounds in animal and human health, crop protection, and urban pest control. Ivermectin has been the most successful antiparasitic drug introduced in animal health and abamectin has been the premier agricultural miticide in recent years.

Macrocyclic lactones affect invertebrates by either directly activating receptors for the neurotransmitters glutamate and GABA, or by potentiating their actions, resulting in an influx of chloride ions into nerve cells and muscle. It is currently believed that the anthelminthic properties of the avermectins are due predominantly to potentiation and/or direct opening of glutamate-gated chloride channels, whereas in insects, it is likely that avermectins bind to multiple sites, including glutamate and GABA-gated chloride channels as well as other insect chloride channels (Sattelle, 1990;

Bloomquist, 1993). The chloride ion flux resulting from the opening by these compounds of chloride channels in invertebrate nerve and muscle, particularly those gated by glutamate and GABA, results in disruption of activity and loss of function in these excitable cells and accounts for the potent actions of these molecules (review: Raymond and Sattelle, 2002). Toxicity is generally greater through ingestion than by residual contact and compared with other neurotoxic agents, macrocyclic lactones are considered to be relatively slow acting. Intoxicated organisms usually die slowly, often over a period of days, and there is no quick knockdown effect. Death usually follows paralysis and immobility. The comparatively poor contact activity of these compounds plus their short environmental persistence generally results in good compatibility with beneficial and nontarget organisms. These compounds have low relative toxicities to vertebrates and are not phytotoxic.

Resistance to avermectins has been demonstrated in a number of arthropods. In most instances, although not clearly determined, resistance is apparently polygenic, develops relatively slowly, and tends to revert rapidly in the absence of selection pressure. Metabolic resistance mechanisms seem to be the most important in the arthropod systems studied to date, and in all these cases a number of biochemical and physiological mechanisms are implicated. Cross-resistance between macrocyclic lactones and other insecticide classes is similarly ill-defined; however, it is apparent that there is little significant cross-resistance. The variations in responses of field strains resistant to other insecticide classes to avermectins may in some cases be due to enhanced metabolism resulting from previous exposure to other insecticides. A number of species have demonstrated wide inherent variation in response to avermectins without the influence of any predisposing factors. This natural variation in susceptibility does not constitute cross-resistance, nor is there evidence to indicate that this variation results in predisposition to develop increased resistance to avermectins.

Despite the widespread, intensive use of abamectin against a number of pests with a high propensity to develop resistance, development of resistance has been relatively slow and rare. The rapid reversion of resistance in the absence of selection pressure and the lack of any confirmed cases of cross-resistance make them amenable for use in resistance management programs. However, in order to prolong the longevity of these compounds in the market place, it will be necessary to minimize selection pressure in practice, especially in high use situations, through proper rotation, good pest management practices, and proper resistance management strategies.

5.3 Neonicotinoid Insecticides

P Jeschke and R Nauen, Bayer CropScience AG,
Monheim, Germany

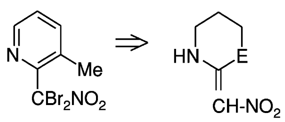
5.3.1. Introduction

The discovery of neonicotinoids as important novel pesticides can be considered a milestone in insecticide research of the past three decades. Neonicotinoids represent the fastest-growing class of insecticides introduced to the market since the commercialization of pyrethroids (Nauen and Bretschneider, 2002). Like the naturally occurring nicotine, all neonicotinoids act on the insect central nervous system (CNS) as agonists of the postsynaptic nicotinic acetylcholine receptors (nAChRs) (Bai *et al.*, 1991; Liu and Casida, 1993a; Yamamoto, 1996; Chao *et al.*, 1997; Zhang *et al.*, 2000; Nauen *et al.*, 2001), but, with remarkable selectivity and efficacy against pest insects while being safe for mammals. As a result of this mode of action there is no cross-resistance to conventional insecticide classes, and therefore the neonicotinoids have begun replacing pyrethroids, chlorinated hydrocarbons, organophosphates, carbamates, and several other classes of compounds as insecticides to control insect pests on major crops (Denholm *et al.*, 2002). Today the class of neonicotinoids are part of a single mode of action group as defined by the Insecticide Resistance Action Committee (IRAC; an Expert Committee of Crop Life) for pest management purposes (Nauen *et al.*, 2001).

Neonicotinoids are potent broad-spectrum insecticides possessing contact, stomach, and systemic activity. They are especially active on hemipteran pest species, such as aphids, whiteflies, and planthoppers, but they are also commercialized to control coleopteran and lepidopteran pest species (Elbert *et al.*, 1991, 1998). Because of their physicochemical properties they are useful for a wide range of different application techniques, including foliar, seed treatment, soil drench, and stem application in

several crops. Due to the favorable mammalian safety characteristics (Matsuda *et al.*, 1998; Yamamoto *et al.*, 1998; Tomizawa *et al.*, 2000) neonicotinoids like imidacloprid are also important for the control of subterranean pests, and for veterinary use (Mencke and Jeschke, 2002).

5.3.2. Neonicotinoid History



In the early 1970s, the former Shell Development Company's Biological Research Center in Modesto, California, invented a new class of nitromethylene heterocyclic compounds capable of acting on the nAChR. Starting with a random screening to discover lead structures from university sources, Shell detected the 2-(dibromo-nitromethyl)-3-methyl pyridine (SD-031588) (**Figure 1**) from a pool of chemicals from Prof. Henry Feuer of Purdue University (Feuer and Lawrence, 1969), which revealed an unexpected low-level insecticidal activity against housefly and pea aphid.

Further structural optimization of this insecticide lead structure led to the active six-membered tetrahydro-2-(nitromethylene)-2*H*-1,3-thiazine, nithiazine (SD-03565, SKI-71) (Soloway *et al.*, 1978, 1979; Schroeder and Flattum, 1984; Kollmeyer *et al.*, 1999). The molecular design by Shell appears rational and straightforward. The chemistry had been largely concentrated on the nitromethylene enamine skeleton (Kagabu, 2003a). Today, this early prototype can be considered as the first generation of the so-called neonicotinoid insecticides (**Figure 2**). Nithiazine showed higher activity than parathion against housefly adults (*Musca domestica*), and 1662 times higher activity against the target insect, the lepidopteran corn earworm larvae (*Helicoverpa zea*), combined with good systemic behavior in plants and low mammalian toxicity (Soloway *et al.*, 1978, 1979; Kollmeyer *et al.*, 1999; Tomizawa and Casida, 2003). However, due to the photochemically unstable 2-nitromethylene chromophore (**Figure 3**) in the field tests, nithiazine was never commercialized for broad agricultural use (Soloway *et al.*, 1978, 1979; Kagabu and Medej, 1995; Kagabu, 1997a; Kollmeyer *et al.*, 1999). Alternatively, photostabilization using the formyl moiety was not adequate for practical application (Kollmeyer *et al.*, 1999). Nevertheless, a knock-down fly product against *M. domestica* containing nithiazine as the active ingredient of a housefly trap device for poultry and animal husbandry has recently been commercialized (Kollmeyer *et al.*, 1999).

In the early 1980s synthesis work was initiated at Nihon Tokushu Noyaku Seizo K. K. (presently Bayer CropScience K. K.) on the basis of this first remarkable neonicotinoid lead structure and the unique insecticidal spectrum of activity (Kagabu *et al.*, 1992; Moriya *et al.*, 1992). Instead of the lepidopteran larva *H. zea*, the target insect for studying structure–activity relationships (SARs) and optimizing biological activity was the green rice leafhopper (*Nephotettix cincticeps*), because it is a major hemipteran pest of rice in Japan (Kagabu, 1997a). At the beginning of the project, a new pesticide screening method using rice seedlings was developed for continuous monitoring of the combined systemic and contact activities of compounds over 2 weeks against leafhoppers and planthoppers (Sone *et al.*, 1995).

The six-membered 2-(nitromethylene)-tetrahydro-1,3-thiazine ring was replaced with different N^1-substituted *N*-heterocyclic ring systems. Starting with 1-methyl-2-(nitromethylene)-imidazolidine, it was found that the activity depends on ring size (5 > 6 > 7-ring system). The N^1-benzylated 2-(nitromethylene)-imidazolidine 5-ring was the most active one. Introduction of substituted benzyl residues in the 1-position, like the *para*-chlorobenzyl moiety, and of nitrogen-containing *N*-hetarylmethyl

residues, like the pyrid-3-ylmethyl moieties, enhanced the insecticidal activity by a factor of 5 and 25 when compared with the N^1-benzylated 2-(nitromethylene)-imidazolidine (Kagabu, 1997a). Yamamoto had previously recognized that the pyrid-3-ylmethyl residue was an essential moiety for insecticidal activity, by referring to the nAChR agonist model of Beers and Reich (1970), and thus synthesized a number of pyrid-3-yl-amines (Yamamoto and Tomizawa, 1993).

This chemical optimization procedure led to discovery of 1-(6-chloro-pyrid-3-ylmethyl)-2-nitro-methylene-imidazolidine (NTN32692), which had over 100-fold higher activity than nithiazine against *N. cincticeps* (using a strain resistant to organophosphorus compounds, methylcarbamates, and pyrethroides) (Kagabu *et al.*, 1992; Moriya *et al.*, 1992). However, the 2-nitromethylene chromophore of NTN32692 absorbs strongly (Figure 3) in sunlight (wavelength 290–400 nm), and rapidly decomposes

in the field to noninsecticidal compounds. In order to avoid absorption of sunlight, a more stable functional group was necessary. After preparation of about 2000 compounds, imidacloprid (NTN33893) containing a 2-(*N*-nitroimino) group (see Section 5.3.3.1.1), the first member of the second-generation neonicotinoids, emerged from this project (Elbert *et al*., 1990, 1991; Bai *et al*., 1991; Nauen *et al*., 2001). The presence of an *N*-nitroimino group at the 2-position of the imidazolidine ring makes little difference to insecticidal activity compared with compounds that contain a nitomethylene group at this position, but the presence of $=N{-}NO_2$ significantly reduces affinity for the receptor (Liu *et al*., 1993b; Tomizawa and Yamamoto, 1993; Yamamoto *et al*., 1998). This suggests that the reduction in binding, resulting from the presence of the nitrogen atom at the 2-position, is compensated by the increase in hydrophobicity, which enhances transport to the target sites (Yamamoto *et al*., 1998; Matsuda *et al*., 2001). Compared with nithiazine, the biological efficacy of imidacloprid against the green rice leafhopper could be enhanced 125-fold. Furthermore, imidacloprid is about 10 000-fold more insecticidal than (*S*)-nicotine, a natural insecticide (Tomizawa and Yamamoto, 1993; Yamamoto *et al*., 1995). This breakthrough to the novel systemic insecticide imidacloprid was achieved by coupling a special heterocyclic group, the 6-chloro-pyrid-3-ylmethyl (CPM) residue (**Figure 4**), to the 2-(*N*-nitroimino)-imidazolidine building-block, new in this class of chemistry.

With the introduction of the insecticide imidacloprid to the market in 1991 Bayer AG began a successful era of the so-called CNI^{TM}s (chloronicotinyl insecticides *syn.* neonicotinoids), a milestone in insecticide research. Imidacloprid has, in the last decade, become the most successful, highly effective, and best selling insecticide worldwide used for crop protection and veterinary pest control.

In connection with these excellent results, a parallel change to other electron-withdrawing substituents like 2-*N*-cyanoimino, having essentially shorter maximum electronic absorptions than 290 nm, led to the discovery of thiacloprid (see Section 5.3.3.1.2), a second member of the CNI group. Attracted by Bayer's success with imidacloprid, several different companies such as Takeda (now Sumitomo Chemical Takeda Agro), Agro Kanesho, Nippon Soda, Mitsui Toatsu (now Mitsui Chemicals, Inc.), Ciba Geigy (now Syngenta), and others initiated intensive research and developed their own neonicotinoid insecticides. Research in these companies was facilitated because neonicotinoid chemistry showed a relatively broad spectrum of activity (Wollweber and Tietjen, 1999; Roslavtseva, 2000). Since the market introduction of imidacloprid, neonicotinoids have become the fastest-growing class of chemical insecticides. This tremendous success can be explained by their unique chemical and biological properties, such as broad-spectrum insecticidal activity, low application rates, excellent systemic characteristics such as uptake and translocation in plants, new mode of action, and favorable safety profile.

5.3.3. Chemical Structure of Neonicotinoids

In general, all these commercialized or developed compounds can be divided into ring systems

containing neonicotinoids, and neonicotinoids having noncyclic structures which differ in their molecular characteristics. Structural requirements for both ring systems containing neonicotinoids and neonicotinoids having noncyclic structures consist of different segments (Nauen *et al.*, 2001): the bridging fragment [R^1–R^2] (i) and for the noncyclic type compounds, the separate substituents [R^1, R^2] (i), the heterocyclic group [Het] (ii), the bridging chain [–CHR–] and the functional group [=X–Y] as part of the pharmacophore [–N–C(E)=X–Y] (iii) (**Figures 2** and **4**, **Table 1**).

The methylene group is normally used as the bridging chain (–CHR– with R = H). Other groups such as an ethylene or substituted methylene group decrease the biological activity. The pharmacophore (iii) can be represented by the group [–N–C(E) =X–Y], where =X–Y is an electron-withdrawing group and E is a NH, NR′, CH_2, O, or S moiety. It is well known that the pharmacophore type influences the insecticidal activity of the neonicotinoids. In general, the greatest insecticidal activity is observed for the compounds containing the nitroenamine (nitromethylene) [–N–C(E)=CH–NO_2; E = S, N], nitroguanidine [–N–C(E)=N–NO_2; E = N], or cyanoamidine [–N–C(E)=N–CN; E = S, CH_3] pharmacophore (Shiokawa *et al.*, 1995). Besides its influence on biological activity, the pharmacophore is also responsible for some specific properties such as photolytic stability, degradation in soil, metabolism in plants, and toxicity to different animals (Kagabu *et al.*, 1992; Moriya *et al.*, 1992; Minamida *et al.*, 1993; Tomizawa and Yamamoto, 1993; Shiokawa *et al.*, 1994; Tabuchi *et al.*, 1994).

The term "neonicotinoid" (Yamamoto, 1998, 1999) was originally proposed for imidacloprid and related insecticidal compounds with structural similarity to the insecticidal alkaloid (*S*)-nicotine, which has a similar mode of action (Tomizawa and Yamamoto, 1993; Tomizawa and Casida, 2003). In addition, a variety of terms have been used to subdivide this chemical class based on structural fragments (**Figure 4**): (a) chloronicotinyls (CNIs, heterocyclic group CPM) (Leicht, 1993), (b) thianicotinyls (heterocyclic group CTM) (Maienfisch *et al.*, 1999a), (c) furanicotinyls (heteroalicyclic group, TFM) (Wakita *et al.*, 2003), (d) nitroimines or nitroguanidines, (e) nitromethylenes, (f) cyanoimines (functional group as part of the pharmacophore), (g) first generation with moiety CPM, (h) second generation with moiety CTM or TFM (Maienfisch *et al.*, 1999a, 2001b), and third generation with moiety TFM (regarding the type of the heterocyclic group) (Wakita *et al.*, 2003).

5.3.3.1. Ring Systems Containing Commercial Neonicotinoids

Ring systems containing neonicotinoids can have as bridging fragment [R^1–R^2] (i) an alkylene group in the building-block, e.g., ethylene for imidacloprid and thiacloprid (five-membered ring systems) which can also be interrupted by heteroatoms like oxygen (six-membered ring systems) as shown in the case of thiamethoxam.

5.3.3.1.1. 1-[(6-Chloro-3-pyridinyl)-methyl]-*N*-nitro-2-imidazolidinimine (imidacloprid, NTN 33893) Imidacloprid was discovered in 1985 as a novel insecticide with a unique structure and with hitherto unrecognized insecticidal performance (Moriya *et al.*, 1992, 1993; Kagabu, 1997a, 2003a). The trade names for soil application/seed treatment are Admire™ and Gaucho® and the trade names for foliar application are Confidor® and Provado®, while for termite control it is Premise® (see Section 5.3.10).

The first laboratory synthesis was carried out by reduction of 6-chloronicotinoyl chloride to 2-chloro-5-hydroxymethyl-pyridine using an excess $NaBH_4$ in water, and conversion to the chloride by $SOCl_2$. Imidacloprid was obtained by the coupling reaction of 2-chloro-5-chloromethyl-pyridine (CCMP) (Diehr *et al.*, 1991; Wollweber and Tietjen, 1999) with the 5-ring building-block 2-nitro-imino-imidazolidine, in acetonitrile with potassium carbonate as base. This method was also successfully applied to the synthesis of [^{3}H]imidacloprid using $NaB[^3H]_4$ (Latli *et al.*, 1996).

Differences in photostability between the 2-nitromethylene group in compound NTN32692 (λ_{max} = 323 nm) and the 2-(*N*-nitroimino) group in imidacloprid (λ_{max} = 269 nm) (**Figure 3**) were examined by quantum chemical methods like AM1 and *ab initio* calculations (Kagabu, 1997a; Kagabu and Akagi, 1997). Crystallographic analysis of imidacloprid revealed a coplanar relationship of the imidazolidine 5-ring to the nitroimino group in position 2 (Born, 1991; Kagabu and Matsuno, 1997). Shorter ring C–N bond lengths and longer exocyclic C=N bond lengths were observed, suggesting the formation of a planar electron delocalized diene system, a so-called push–pull olefin (Kagabu and Matsuno, 1997). An intramolecular hydrogen bond between $^1NH \cdots O_2N{-}N{=}C^2$ was confirmed by characteristic resonances in the nuclear magnetic resonance (NMR) spectra (correlation spectroscopy (COSY), nuclear overhauser enhancement spectroscopy (NOESY)). In addition, the infrared (IR) spectrum showed a highly chelated ^{1}NH absorption by intense bands at 3356 and 3310 cm^{-1} (Kagabu *et al.*, 1998).

[b] DuPont.

Studies were also done using comparative molecular field analysis (CoMFA), a technique for analysis of three-dimensional quantitative structure–activity relationships (3D QSAR) (Cramer *et al.*, 1988; Okazawa *et al.*, 1998). The model showed that the nitrogen atom of the imidacloprid CPM residue interacts with a hydrogen-donating site of nAChR, and the nitrogen atom at the 1-position of the imidazolidine 5-ring interacts with a negatively charged domain (Okazawa *et al.*, 2000). In comparison with (*S*)-nicotine the selective insecticidal mode of action of imidacloprid was well examined in detail by different researchers (Yamamoto *et al.*, 1995; Kagabu, 1997b; Matsuda *et al.*, 1999; Tomizawa, 2000). There studies focused on the chemical structure, state of ionization, and hydrophobicity of both molecules (**Figure 5**).

The principal target insect pests of imidacloprid in agricultural and veterinary medicinal use are sucking insects. Since imidacloprid provides a partial positively charged δ^+ nitrogen atom (not ionized, full or partial) instead of an ammonium head as does (*S*)-nicotine, imidacloprid has little restriction for translocation into the target area compared to (*S*)-nicotine (Graton *et al.*, 2003). The interatomic distances between the 2-(*N*-nitroimino)-imidazolidine nitrogen and the pyridyl nitrogen are 5.9 Å, which is a suitable value to bind to the electron-rich and hydrogen-donating recognition sites on nAChR (Yamamoto *et al.*, 1995; Matsuda *et al.*, 1999). The electron-donating atom for hydrogen bonding at 5.9 Å apart from the fully or partial positive charged δ^+ nitrogen is required for potent interaction with the anionic subsite of the insect nAChR (Yamamoto *et al.*, 1995; Tomizawa, 2000). In mammals, imidacloprid has weak effects on any nAChR, while nicotine affects mostly peripheral nACRs resulting in higher toxicity.

The deduced electron deficiency of the nitrogen atom of imidacloprid was proved explicitly by ^{15}N NMR spectroscopic measurements (Yamamoto *et al.*, 1995). Tomizawa *et al.* (2000) recently claimed that the *N*-nitro group of imidacloprid is much more important than the bridgehead nitrogen in electrostatic interaction with nAChRs' because a Mulliken charge of the bridgehead nitrogen, calculated by the MNDO method combined with the PM3 method (semi-empirical molecular orbital technique

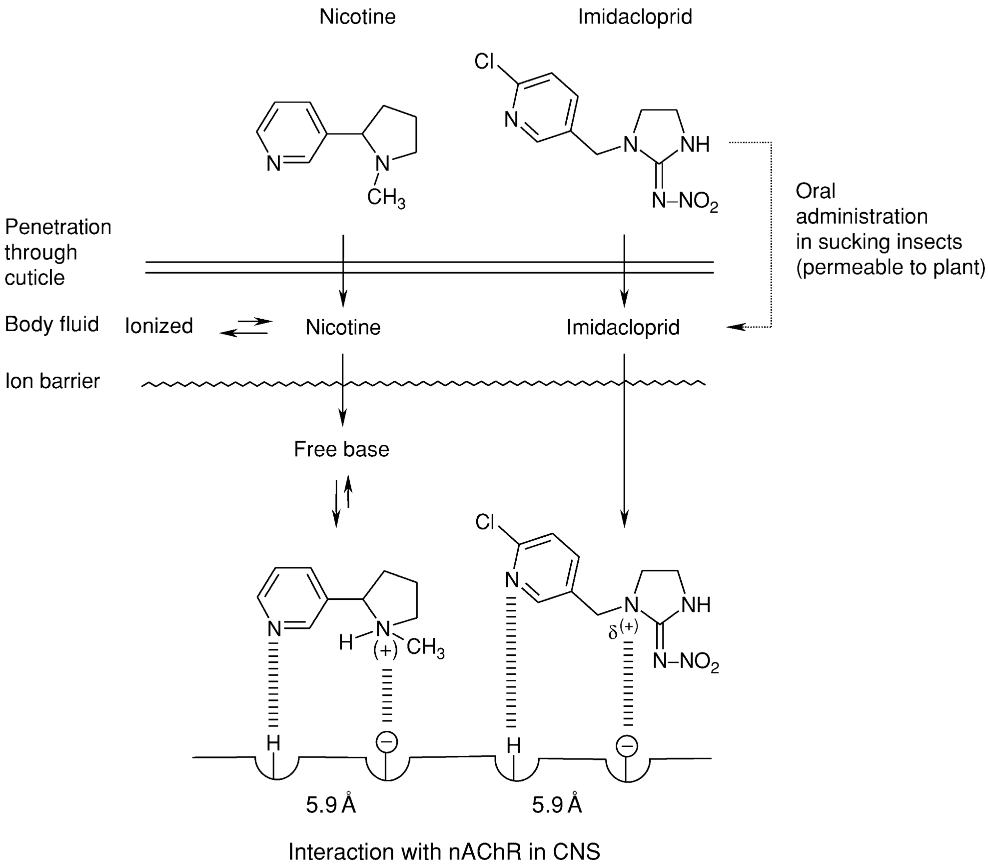

Figure 5 Insecticidal mode of action of (*S*)-nicotine and imidacloprid. (Adapted from Tomizawa, M., **2000**. Insect nicotinic acetylcholine receptors: mode of action of insecticide and functional architecture of the receptor. *Jap. J. Appl. Entomol. Zool. 44*, 1–15.)

for calculating electronic structure), was only marginally positive. However, Matsuda *et al*. (2001) suggested, that the electron-withdrawing power of the *N*-nitro group might be increased by a hydrogen bond involving the *N*-nitro group oxygen and hydrogen-bondable and positively charged amino acid residue, namely lysine or arginine, on the insect receptor, thereby strengthening its interaction with imidacloprid. Kagabu (1996) predicted the important contribution of this *N*-nitro group and its hydrogen-bondable property for insecticidal activity.

5.3.3.1.2. [3-(6-Chloro-3-pyridinyl)methyl-2-thiazolidinylidene]-cyanamidine (thiacloprid, YRC 2894) The second member of the CNI™ family from Bayer AG launched in 2000 was thiacloprid (Elbert *et al*., 2000; Yaguchi and Sato, 2001). Similar to imidacloprid, this neonicotinoid thiacloprid (YRC 2894, registered worldwide under the trade name Calypso™, and in Japan and Switzerland under the trade names Bariard™ and Alanto™), also contains the unique CPM moiety attached to the cyclic 2-(cyanoimino)-thiazolidine (CIT) building-block. Thiacloprid can be synthesized by a convergent one-step technical process starting from two key intermediates, CIT and CCMP (Diehr *et al*., 1991; Wollweber and Tietjen, 1999; Jeschke *et al*., 2001). Thiacloprid crystallizes in two different modifications depending on the solvent. The compound crystallizes from dichloromethane as form I (melting point 136 °C) and from isopropanol as form II (melting point 128.3 °C). From its physicochemical data, the technical ingredient is form I. The results of X-ray crystallographic analysis and an X-ray powder diffraction profile indicate that each form, I ($0.6 \times 0.3 \times 0.2\,mm^3$) and II ($0.5 \times 0.2 \times 0.1\,mm^3$), crystallizes with different cell constants in a monoclinic crystal system in the space group $P2_1/c$ (Jeschke *et al*., 2001). **Figure 6** shows the Ortep plot of the crystal structure of the form I. Interestingly, in the crystal lattice of form II, two symmetric independent molecules in the asymmetric unit cell are fixed (**Figure 6**).

With regard to the configuration of the pharmacophore [–N–C(S)=N–CN] moiety, thiacloprid exists only in the *Z*-configuration in both forms, I and II. In conjunction with the X-ray results, thiacloprid exists in solution exclusively in the stable *Z*-configuration. With respect to the C=N double bond, only one configuration is seen in all NMR spectra (^1H, ^{13}C, HMQC, HMBC, NMR spectroscopy), deduced from very sharp proton and carbon signals. In conjunction with X-ray results, there is no evidence for isomerization of the *Z*-isomer in DMSO-d_6 or $CDCl_3$ solution. Thiacloprid shows a single peak maximum at 242 nm in its ultraviolet (UV) spectrum, and it does not absorb natural sunlight. This explains thiacloprid's better photostability in comparison to other neonicotinoids (Jeschke *et al*., 2001).

Starting from forcefield methods (MMFF94s), the final energies, geometries, and properties were obtained at DFT (Becke and Perdew (BP) functional, triple-zeta valence plus (TZVP) polarization basis, conductor-like screening model – realistic solvent (COSMO-RS) for solvent effects; Perdew, 1986;

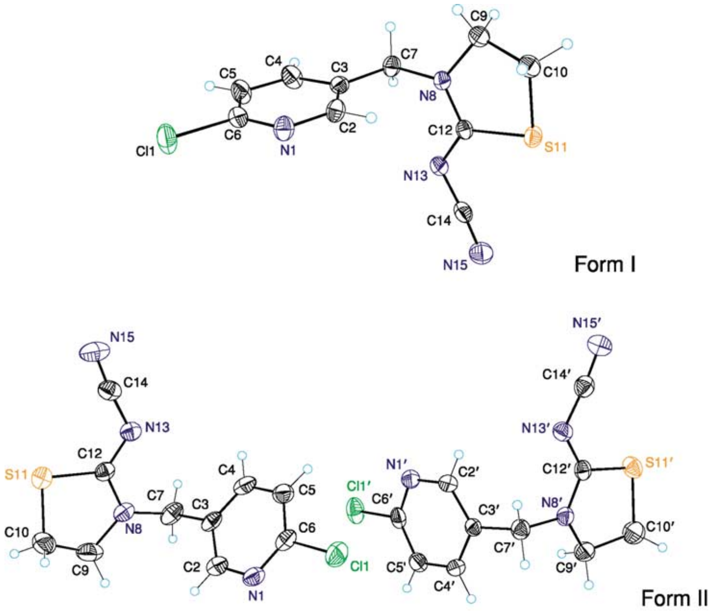

Figure 6 Ortep plot of thiacloprid form I and form II (Jeschke *et al*., 2001).

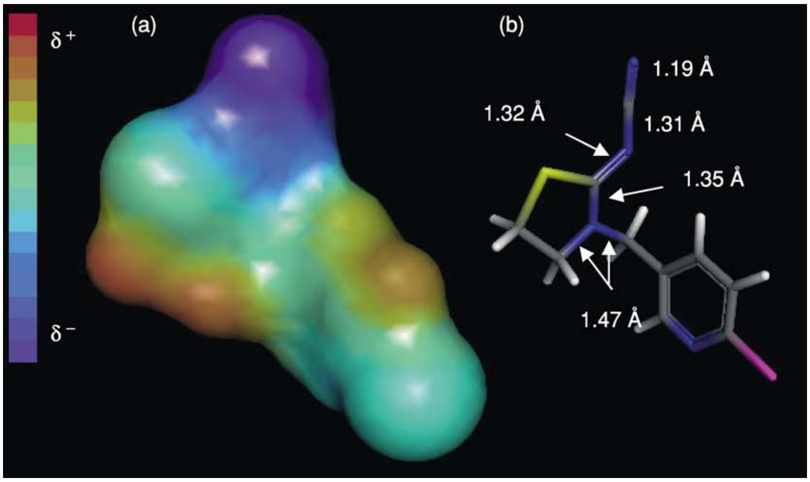

Figure 7 DFT (BR/TZVP) optimized geometry of thiacloprid (Jeschke *et al.*, 2001). (a) Atomic charges projected onto a Conolly surface; (b) some interatomic distances in Å.

Becke, 1988; Klamt, 1995) level of theory (Jeschke *et al.*, 2001) (**Figure 7**). It was found that, in the gas phase, *Z*-configured thiacloprid is about 4 kcal mol^{-1} lower in energy than the *E*-isomer. In water, this difference is increased by approximately 1 kcal mol^{-1}. The preference for the *Z*-configuration stems mainly from steric reasons. The nitrile moiety of the *Z*-isomer has virtually no close contacts to any other atom (sulfur to nitrile-carbon distance 3.1 Å). In the *E*-isomer, however, the largest possible distance, between the nitrile-carbon and the hydrogen atoms attached to the bridging carbon, is around 2.3 Å. Quantum chemical calculations show that the strong delocalization of the C=N double bond does not reduce the "double bond character" significantly (i.e., the torsional barrier for rotation around the C=N double bond is not decreased). The molecular dipole moment (derived from the electric field dependence of the DFT wave function) is calculated to be 10.2 D in water. This, together with the spatial relation of the pharmacophoric feature (–N–C(S)=N–CN), is very much in line with the pharmacophore model of imidacloprid.

5.3.3.1.3. 3-[(2-Chloro-5-thiazolyl)methyl]tetrahydro-5-methyl-*N*-nitro-4H-1,3,5-oxadiazin-4-imine (thiamethoxam, CGA 293′343) Ciba started a research program on neonicotinoids in 1985 (Maienfisch *et al.*, 2001a), and investigated variations of the imidacloprid nitroimino-heterocycle (Maienfisch *et al.*, 2001b). Thiamethoxam (Senn *et al.*, 1998; Maienfisch *et al.*, 1999a, 1999b) was discovered, and developed by Ciba Crop Protection (from 1996 Novartis Crop Protection, now Syngenta Crop Protection) in 1991. Thiamethoxam has been marketed since 1998 under the trademarks Actara® for foliar and soil treatment, and Cruiser® for seed treatment. Thiamethoxam can be synthesized starting from *N*-methyl-nitroguanidine by treatment with formaldehyde in the presence of formic acid (Göbel *et al.*, 1999). Finally alkylation with 2-chlorothiazol-5-ylmethylchloride in *N*,*N*-dimethyl-formamide and potassium carbonate as a base afforded the active ingredient in good yields (Maienfisch *et al.*, 1999a).

The SAR profile of this compound demonstrates the rather limited variability of the pharmacophore (–N–C(N)=N–NO_2). Insecticidal activity was only observed if the functional group is a strongly electron-withdrawing group and has a hydrogen accepting head, like *N*-nitroimino and *N*-cyanoimino. As pharmacophore *N*-substituent, a methyl group is clearly superior to hydrogen, an acyl substituent or C_2–C_4 alkyl group. The biological results have led to a general SAR profile for these novel compounds, which can be summarized as follows (Maienfisch *et al.*, 1999b, 2002):

1. All variations of the pharmacophore (N–C(N)=N–NO_2) resulted in a loss of activity.
2. Substitution of the CTM moiety by another N-containing heterocycle reduced the overall insecticidal activity, whereas CPM gave the best results.
3. A perhydro-1,3,5-oxadiazine ring system is clearly better than all other heterocyclic systems like perhydro-1,3,5-thiadiazines, hexahydro-1,3,5-triazines, or hexahydro-1,3-diazines.
4. Introduction of *N*-methyl at the 5-position led to strong increase of insecticidal activity (in contrast to the SAR of imidacloprid), whereas other substituents resulted in clear loss of activity.

5.3.3.2. Neonicotinoids Having Noncyclic Structures

From the new chemical class of ring system containing neonicotinoids noncyclic structures having the same mode of action can also be deduced. These noncyclic type neonicotinoids can have as separate substituents [R^1, R^2] (i), e.g., for R^1 hydrogen or alkyl like methyl (acetamiprid) and ethyl (nitenpyram) and in the case of E = NH for the substituent R^2 alkyl like methyl (clothianidin and dinotefuran), respectively.

5.3.3.2.1. *N*-[(6-chloro-3-pyridinyl)methyl]-*N*-ethyl-*N*′-methyl-2-nitro-1,1,-ethenediamine (nitenpyram, TI-304) Starting from the cyclic nithiazine (Soloway *et al*., 1978), the acyclic nitenpyram (Bestguard™) was discovered during optimization of substituents of an acyclic nitroethene (Minamida *et al*., 1993). The insecticidal activity of 1-(3-pyridylamino)-2-nitroethene compounds against the brown planthopper and the green leafhopper were studied. It was found that the 1-methylamino-1-(pyrid-3-ylmethylamino)-2-nitroethene was more active than the corresponding 1-ethyl, 1-methoxy, or 1-thiomethoxy derivatives. Introduction of sterically large amino groups like ethylamino, isopropylamino, hydrazino, *N*-pyrrolidino, or N-morpholino decreased the activity against the green rice leafhopper. Furthermore, the methylene bridge between the pyrid-3-yl and nitrogen was replaced with other linkages. However, all attempts at shortening and lengthening the linkage failed to increase the insecticidal activities against the brown planthopper and the green rice leafhopper (Akayama and Minamida, 1999). Heterocyclic aromatic substituents, different from pyrid-3-yl, were incorporated into the nitroethen structure. The replacement of pyrid-3-yl with 6-fluoro-pyrid-3-yl, 6-chloro-pyrid-3-yl, 6-bromo-pyrid-3-yl, and 2-chloro-1,3-thiazol-5-yl enhanced the activity against the brown planthopper.

5.3.3.2.2. (*E*)-*N*-[(6-chloro-3-pyridinyl)methyl]-*N*′-cyano-*N*-methyl-ethanimidamide (acetamiprid, NI-25) Acetamiprid (Takahashi *et al*., 1992; Matsuda and Takahashi, 1996) has an *N*-cyanoamidine structure, which contains in analogy to imidacloprid and thiacloprid the CPM moiety. This neonicotinoid was invented during a search for nitromethylene derivatives by Nippon Soda Co. Ltd. in 1989 and was registered in 1995 in Japan. The insecticide is marketed under the trade name Mospilan® for crop protection. The noncyclic acetamiprid was discovered by optimization studies of special 2-*N*-cyanoimino compounds with an imidazolidine 5-ring obtained from Nihon Bayer (Yamada *et al*., 1999). The noncyclic 2-nitromethylene and 2-*N*-nitroimine derivatives are less active than the corresponding ring structures, but numerous noncyclic derivatives show excellent activities against the armyworm and aphid as well as the cockroach. Regarding the substituent on the amino group, the *N*-methyl group exhibited the highest activity against the diamondback moth, while derivatives with hydrogen, *N*-methyl, and *N*-ethyl showed potent activity against the cotton aphid (Yamada *et al*., 1999).

5.3.3.2.3. [C(*E*)]-*N*-[(2-chloro-5-thiazolyl)methyl]-*N*′-methyl-*N*″-nitroguanidine (clothianidin, TI-435) As a result of continuous investigations of noncyclic neonicotinoids, researchers from Nihon Bayer Agrochem and Takeda in Japan found that these noncyclic neonicotinoids showed high activities against sucking insects. In the optimization process, Takeda researchers were able to demonstrate that compounds containing the nitroguanidine moiety, coupled with the thiazol-5-ylmethyl residue, have increased activity against some lepidopteran pests (Uneme *et al*., 1999). This is in accordance with the general pharmacophore [–N–C(E)=X–Y], where =X–Y is an electron-withdrawing group such as =N–NO_2, and E represents the NH–Me unit. After further optimization in this subclass, clothianidin (TI-435) emerged as the most promising derivative from this program (Ohkawara *et al*., 2002; Jeschke *et al*., 2003). Clothianidin has already been registered in Japan for foliar and soil applications under the trade names Dantotsu™ and Fullswing™ (Sumitomo Chemical Takeda Agro), and also in Korea, Taiwan, and other countries. Registrations have also been granted in North America and Europe for seed treatment under the brand name Poncho® (Bayer CropScience).

In the novel noncyclic structure of clothianidin (TI-435) (i.e., R = H; E = NHMe), the *N*-nitroguanidine pharmacophore [–N–C(N)=N–NO_2] is similar to that of imidacloprid, but the CPM group has been replaced by the CTM moiety (Ohkawara *et al*., 2002) (**Figure 2**). Clothianidin crystallizes under normal laboratory conditions using common solvents as needlelike crystals containing no additional solvent or water molecules. The best-quality crystals for X-ray structure analysis were obtained by slow evaporation of a methanol/H_2O (1 : 1) solution at room temperature. **Figure 8** shows a photograph using polarized light of the crystal needle with the dimensions $0.90 \times 0.30 \times 0.07\ mm^3$ used for X-ray structure analysis (Jeschke *et al*., 2003). Clothianidin (TI-435) was subjected to conformational sampling using forcefield methods (MMFF94s).

The calculated free energies indicate that at room temperature (RT), the preferred orientation of the *N*-nitroimino group is in the *trans* position; the *Z*-isomer with lowest energy is more than 2.6 kcal mol^{-1} above the optimal *E*-isomer. NMR experiments are in agreement that the *N*-nitroimino group strongly prefers one orientation only. From calculations as well as the X-ray structure, one can see that the three C–N bonds involving atom C5 have some double bond character. It is worth mentioning that the C5–N3 bond, which is the only formal C=N double bond within the *N*-nitroimino moiety, is slightly longer than the formal single bonds C5–N5 and C5–N2. This is reflected by the torsional angles found around the C–N bonds during conformational analysis; the respective values are all 180° or −180°. The *N*-methyl group can flip easily from the anti position into a syn position. The energies of the respective clothianidin (TI-435) conformers, relative to the optimal structure, are below 1.5 kcal mol^{-1}. All these findings are in line with the experimental ^{13}C NMR spectrum, which shows a relatively broad singlet at 138.8 ppm for the atom C3. This can already be understood qualitatively from the conformational arguments, like rotations of the C–N single bonds and modifications of the positioning of the CTM moiety (Jeschke *et al.*, 2003).

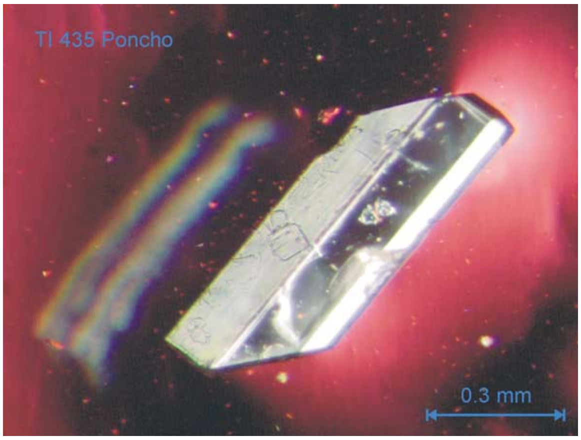

Figure 8 Digital stereo photomicrograph of a single crystal of clothianidin (TI-435) grown from methanol/water at room temperature (Jeschke *et al.*, 2003).

5.3.3.2.4. (±)-*N*-methyl-*N*′-nitro-*N*″-[(tetrahydro-3-furanyl)methyl]guanidine (dinotefuran, MTI-446) (±)-Dinotefuran (MTI-446) was discovered by Mitsui Chemicals Inc., and is highly effective as an agonist of nAChRs (Zhang *et al.*, 2000). It has a broad spectrum of activity against insect pests and has low mammalian toxicity (Kodaka *et al.*, 1998, 1999a, 1999b; Hirase, 2003). The trade names for the commercialized product are Starkle® and Albarin®. Similar to imidacloprid and clothianidin, it has a *N*-nitroguanidine pharmacophore [–N–C(N)=N–NO_2], but an alicyclic (±)-tetrahydro-3-furylmethyl (TFM) moiety instead of the halogenated heteroaromatic CPM or CTM moiety in the other neonicotinoids. The discovery of (±)-dinotefuran resulted from the idea of incorporating an *N*-nitroimino fragment into the structure of acetylcholine (Kodaka *et al.*, 1998; Wakita *et al.*, 2003). (±)-Dinotefuran bears a nonaromatic oxygen atom in the position corresponding to that of the aromatic nitrogen atom of the other neonicotinoids. The potencies of (±)-dinotefuran and a competitive nAChR antagonist (α-bungarotoxin, BGT) in inhibiting [^{3}H]epibatidine binding to *Periplaneta americana* nerve cord membranes were examined (Mori *et al.*, 2001). (±) and (+) Dinotefuran inhibited [^{3}H]epibatidine binding with IC_{50} (inhibitory concentration, where 50% of the tritiated ligand is displaced in membrane preparations from cockroach nerve) values of 890 and 856 nM, respectively. The (−)-enantiomer was about twofold less effective. In contrast the (+)-enantiomer was approximately 50-fold more insecticidal than the (−)-enantiomer of dinotefuran (Table 2).

The SAR between the tetrahydrofuran ring moiety and the insecticidal activity was investigated (Kiriyama and Nishimura, 2002), and it was found that:

Table 2 Potency of dinotefuran and its isomers in inhibiting [^{3}H]EPI and [^{3}H]α-BGT binding, and their *in vivo* activities

Compound	*[^{3}H]EPI binding, IC_{50} (nM)[a]*	*[^{3}H]α-BGT binding, IC_{50} (nM)[a]*	*Knockdown, KD_{50} (nmol g^{-1})*	*Insecticidal activity, LD_{50} (nmol g^{-1})[a]*
(±)-Dinotefuran	890 (626–1264)	36.1 (24.9–52.2)	0.351	0.173 (0.104–0.287)
(+)-Dinotefuran	856 (590–1241)	9.58 (6.79–13.52)	0.123	0.0545 (0.0396–0.0792)

Reproduced with permission from Mori, K., Okumoto, T., Kawahara, N., Ozoe, Y., **2001**. Interaction of dinotefuran and its analogues with nicotinic acetylcholine receptors of cockroach nerve cords. *Pest Mgt Sci. 58*, 190–196.

1. The tetrahydro-fur-2-ylmethyl derivative (shift of oxygen position) reflected diminished activity.
2. The tetrahydro-fur-3-yl moiety is important; the cyclopentanylmethyl (deoxy derivative), the 3-methoxy-*N*-propyl (open-ring ether) and the *N*-methyl-pyrrolidine-3-ylmethyl derivatives showed very low or negligible activity.
3. Introduction of a methyl group at the 4- or 5-position of the tetrahydro-fur-3-yl ring gave intermediate activity (Wakita *et al*., 2003), but introduction of methyl at the 2- or 3-position of the THF ring system and in α-position of the side chain decreases activity. An ethyl group reduced greatly activity even if it was at the 4-position (Wakita *et al*., 2003).

The structural factors in the *N*-nitro guanidine moiety of (±)-dinotefuran were described as follows:

1. Deletion or extension to the alkyl group, like ethyl, of the terminal *N*-methyl group and addition of one more *N*-methyl group usually decrease the activity.
2. Carbocyclic cyclization to 5- and 6-ring systems maintains the activity.
3. Perhydro-1,3,5-oxadiazine 6-ring cyclization similar to that in thiamethoxam is inactive.
4. Modification of the *N*-nitroimino chromophore of dinotefuran to the nitromethylene, but not to the *N*-cyanoimino group maintains the insecticidal activity.

These results indicate that the modification of this moiety of (±)-dinotefuran results in drastic changes in potency and that the incorporation of structural fragments known from previous neonicotinoid insecticides does not necessarily lead to compounds retaining higher activity (Mori *et al*., 2001). Also in this structural type the distance of three methylene chains between the nitrogen on the imidazolidine ring and the hydrogen acceptor oxygen was important (Wakita *et al*., 2003).

5.3.3.3. Bioisosteric Segments of Neonicotinoids

Retrospective considerations regarding bioisosteric segments of the developed and commercial neonicotinoids gave insight into general structural requirements (segments i–iii, **Figure 4**) for all the different ring systems and noncyclic structures (Jeschke *et al*., 2002). Several common molecular features, when comparing compounds with ring systems, like imidazolidine (imidacloprid), and its isosteric alternatives, like thiazolidine (thiacloprid), perhydro-1,3,5-oxadiazine (thiamethoxam), or hexahydro-1,3,5-triazine (Agro Kanesho's AKD-1022) and the functional groups like *N*-nitroimino [=N–NO_2], *N*-cyanoimino [=N–CN], or nitromethylene [=CH–NO_2] of these insecticides, have been described (Tomizawa *et al*., 2000). After superposition of the most active derivatives, it was possible to state the molecular shape similarity of the second generation neonicotinoids. It was found that electrostatic similarity of the most active compounds correlates well with the binding affinity (Nakayama and Sukekawa, 1998; Sukekawa and Nakayama, 1999), and a similar correlation was obtained by CoMFA (Nakayama, 1998; Okazawa *et al*., 1998).

5.3.3.3.1. Ring systems versus noncyclic structures

In comparison to the corresponding ring systems, the noncyclic structures exhibit similar broad insecticidal activity by forming a so-called quasi-cyclic conformation when binding to the insect nAChR (Kagabu, 2003a). Thus, the three commercial noncyclic structures – nitenpyram, acetamiprid, and clothianidin – can be regarded as examples, if retrosynthetic considerations are carried out (Jeschke *et al*., 2002; Kagabu, 2003a). The noncyclic neonicotinoides are generally less lipophilic than the corresponding neonicotinoids with a ring structure (see Section 5.3.3.4).

Based on the CoMFA results, a binding model for imidacloprid was described. This model clarified that the nitrogen of the CPM moiety interacts with a hydrogen-donating site of the nAChR, and that the nitrogen atom at the 1-position of the imidazolidine ring interacts with the negatively charged domain (Nakayama, 1998; Okazawa *et al*., 1998). Furthermore, the binding activity of noncyclic structures (e.g., acetamiprid, nitenpyram, and related compounds) to the nAChR of houseflies was measured and the results were analyzed using CoMFA. Superposition of stable conformations of nitenpyram, acetamiprid, and imidacloprid showed that the preferred regions for negative electrostatic potentials near the oxygen atoms of the nitro group, as well as the sterically forbidden regions beyond the imidazolidine 3-nitrogen atom of imidacloprid, were important for binding (Okazawa *et al*., 2000). The area around the 6-chloro atom of the CPM moiety was described as a sterically permissible region. Apparently the steric interactions were more important for noncyclic neonicotinoids than for the cyclic derivative, imidacloprid. Finally, it was also demonstrated that the noncyclic structures bind to the nAChR recognition site in a manner similar to ring structures like imidacloprid, and that the electrostatic properties of the noncyclic amino and cyclic imidazolidine structures affected their binding affinity (**Figure 9**).

Figure 10 shows atom-based aligments of imidacloprid, clothianidin, dinotefuran and acetamiprid.

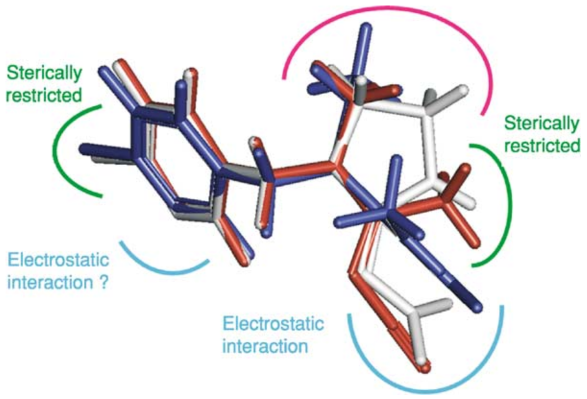

Figure 9 Stable conformations and predicted properties of binding site: imidacloprid (white), nitenpyram (blue), acetamiprid (red). (Adapted from Akazawa *et al.*, 2000.)

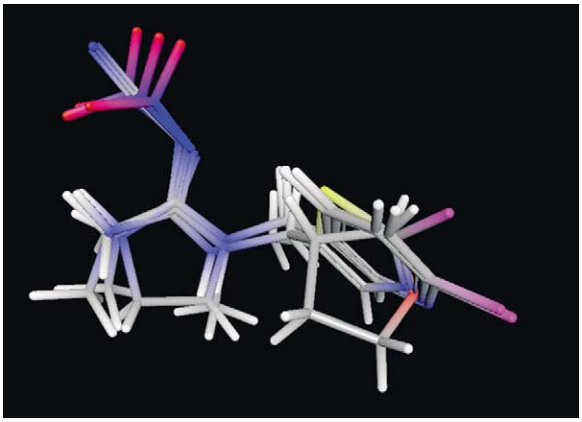

Figure 10 Alignment of DFT/BP/SVP/COSMO optimized geometries of imidacloprid, clothianidin, dinotefuran, and acetamiprid. The alignment was done by minimization of the mutual spatial distance of three pharmacophoric points, namely (i) the positively charged carbon atom connected to the =N–NO_2 and =N–CN moiety, respectively, (ii) the nitro/cyano groups themselves, and (iii) the nitrogens of the aromatic rings and the oxygen of the tetrahydrofuran ring.

The aligment shown does not necessarily reflect the active conformation. However, the following arguments hold true for each of these family of conformers. The ion pairs of the aromatic nitrogen atoms in imidacloprid, clothianidin, and acetamiprid point in the same direction, and that this is also true for one of the two ion pairs of oxygen in dinotefuran. The tetrahydrofuryl ring of dinotefuran is more or less perpendicular to the heteroaromatic ring systems of the other neonicotinoids.

Visual inspection of the nucleophilic Fukui functions (**Figure 11**) shows that the tetrahydrofuryl ring of dinotefuran differs dramatically from the other neonicotinoids under investigation. While the latter all show some large contributions at the aromatic moiety, the tetrahydrofuryl moiety seems to be much less attractive for nucleophilic attack.

5.3.3.3.2. Isosteric alternatives to the heterocyclic *N*-substituents The nitrogen-containing hetarylmethyl group as *N*-substituent (CPM, CTM) has a remarkably strong influence on the insecticidal activity. X-ray crystal structure analysis of imidacloprid and related neonicotinoids indicated that distances between the van der Waals surface of the CPM nitrogen and the atomic center of the pharmacophoric nitrogen are 5.45–6.06 Å (Tomizawa *et al.*, 2000). This range coincides with the distance between the ammonium nitrogen and carbonyl oxygen of acetylcholine, and between the nitrogen atoms of (*S*)-nicotine (Kagabu, 1997a). Alternatively, the CPM and CTM moieties were assumed to be able to participate in hydrogen bonding, like the pyridine ring of (*S*)-nicotine, and that this is important for the insecticidal activity. The CTM substituent generally confers higher potency in the clothianidin and *N*-desmethyl-thiamethoxam series than the CPM moiety in the imidacloprid, thiacloprid, acetamiprid, and nitenpyram series (Zhang *et al.*, 2000). Surprisingly, replacing both CPM and CTM by an oxygen-containing five-membered heterocycle resulted in a novel *N*-substituent TFM, that led to the development of the insecticide (±)-dinotefuran. It was found that the TFM structure can be taken as an isoster of the CPM and CTM moiety (Kagabu *et al.*, 2002). In an attempt to understand this, the hydrogen bonding regions of CPM, CTM, and TFM were projected onto their respective Connolly surfaces (Jeschke *et al.*, 2002) (**Figure 12**).

5.3.3.3.3. Bioisosteric pharmacophors The particularly high potency of the neonicotinoids bearing *N*-nitroimino, *N*-cyanoimino, or nitromethylene moieties, which have a negative electrostatic potential, implies a positive electrostatic potential for the corresponding insect nAChR recognition site (Nakayama and Sukekawa, 1998). Therefore, considerable attention has been given to the possible involvement of the pharmacophoric nitrogen in neonicotinoid action. In order to understand better the structural requirements, binding activity was analyzed using CoMFA (Akamatsu *et al.*, 1997). SAR analyses have also been performed for *in vitro* activities (Nishimura *et al.*, 1994). In particular, 3D QSAR procedures are helpful to predict the receptor–ligand interaction (Nakayama, 1998; Okazawa *et al.*, 1998,

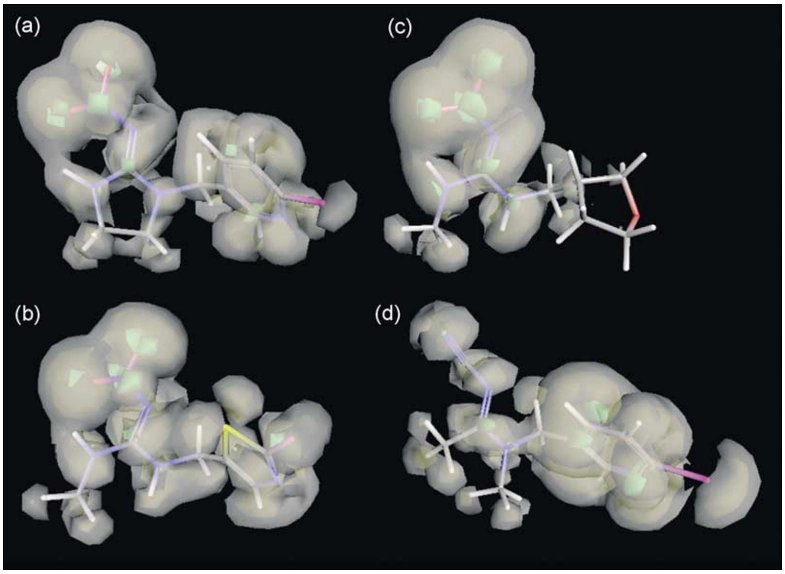

Figure 11 Isosurfaces for Fukui functions for nucleophilic attack of (a) imidacloprid, (b) clothianidin, (c) dinotefuran, and (d) acetamiprid. Three levels of isosurfaces are displayed: 0.005 (green, opaque), 0.001 (yellow, transparent), and 0.0005 (white, transparent).

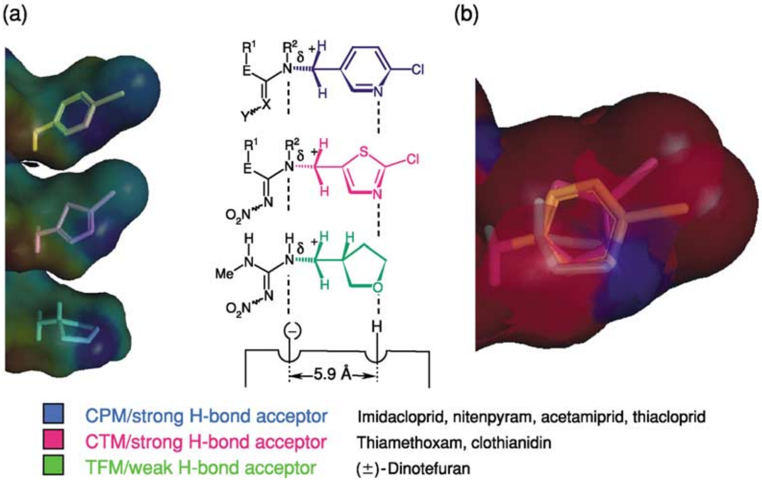

Figure 12 Isosteric alternatives to the heterocyclic *N*-substituents. Connolly surfaces of the CPM moiety from imidacloprid, nitenpyram, acetamiprid (blue), CTM moiety from thiamethoxam and clothianidin (magenta), and TFM from (±)-dinotefuran (green). Atomic charges have been driven via the Mulliken partitioning scheme DFT/BP/TZVP/COSMO Kohn–Sham orbitals. (a) H-bonding potentials is mapped onto the Connolly surface; (b) atomic charges are projected onto the Connolly surface. (Reproduced with permission from Jeschke, P., Schindler, M., Beck, M., **2002**. Neonicotinoid insecticides: retrospective consideration and prospects. *Proc. BCPC: Pests and Diseases 1*, 137–144.)

2000).

As described in an alternative binding model for imidacloprid, the interatomic distance of 5.9 Å between the oxygen of the nitro group (at the van der Waals surface) and the nitrogen in 1-position was also noted as adequate (Kagabu, 1997a). That means the oxygen of the nitro group and the cyano nitrogen are well suited as acceptors for hydrogen bonding with the nAChR, in place of ring nitrogen atoms in CPM and CTM or the ring oxygen in TFM. Thus the π-conjugated system composed of a *N*-nitroimino or *N*-cyanoimino group and the conjugated nitrogen in 1-position are considered essential moieties for the binding of neonicotinoids to the putative cationic subsite in insect nAChR (**Figure 13**). On the other hand, Maienfisch *et al.* (1997) reported that a nitroenamine isomer (N^3-free

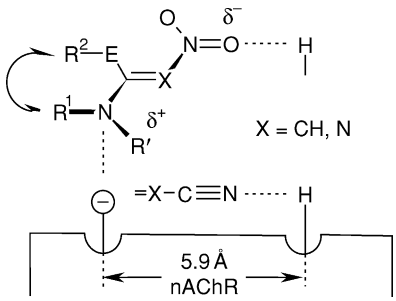

Figure 13 Binding to putative cationic subsite in insect nAChR (Kagabu, 1997a).

imidacloprid) posseses similar insecticidal activity to imidacloprid (Boëlle *et al.*, 1998).

5.3.3.4. Physicochemistry of Neonicotinoids

The physicochemical properties of the ring system and noncyclic neonicotinoids played an important role in their successful development. In addition, photostability is a significant factor in field performance of this class of insecticides (see Section 5.3.2). As described (Kagabu and Medej, 1995; Kagabu, 1997a; Kagabu and Akagi, 1997), the energy gap for the different functional groups [=X–Y], from the ground state to the single state, excited in the order [=N–CN] > [=N–NO_2] > [=CH–NO_2]. For practical application of neonicotinoids, such as for soil and seed treatment, as well as for foliar application, the uptake and translocation in plants is crucial for their insecticidal activity. Thereby, not only the bioisosteric segments of neonicotinoids (see Section 5.3.3.3.3) but also the whole molecular shape (**Figure 12**), including the resultant water solubility, has to be considered. Neonicotinoid insecticides are push–pull olefins made up of conjugated electron donating and accepting groups (Kagabu, 1997a). Such polar, nonvolatile molecules have a high water solubility (**Table 3**) and low P_{OW} values compared with other nonpolar insecticidal classes. The following characteristics were described from Kagabu (1997a):

1. Noncyclic neonicotinoids are less lipophilic than the corresponding ring system neonicotinoids.
2. Concerning the functional group [=X–Y] as part of the pharmacophore [–N–C(E)=X–Y] (iii), water solubility increases in the order of [=CH–NO_2] > [=N–CN] > [=N–NO_2].
3. Regarding E, the lipophilicity increased in the order of S > C > O > NH (Kagabu, 1996).

Somewhat more lipophilic neonicotinoids should be better for seed treatment application, because uptake by roots is more effective than in the case of more hydrophilic compounds (Briggs *et al.*, 1982) (**Figure 14**, **Table 3**). Due to the excellent systemic properties of neonicotinoids conferred by the moderate water solubility, these insecticides are effective against their main target pests, which are sucking insects, like aphids, leafhoppers, and whiteflies.

5.3.3.4.1. Physicochemical properties of commercialized neonicotinoids The physicochemical properties of a compound are related to its structural formula. However, it is not possible to predict the behavior of a substance, with sufficient certainity, only on the basis of its formula and physicochemical properties (Stupp and Fahl, 2003).

5.3.3.4.1.1. Imidacloprid Due to the special moieties like the CPM residue and the 2-(*N*-nitroimino)-imidazolidine 5-ring system, imidacloprid has very weak basic properties under environmental conditions (see Section 5.3.8.1.2). Water solubility and low partition coefficient in octanol–water are not influenced by pH values between 4 and 9, and at 20 °C (Krohn and Hellpointer, 2002) (**Table 3**). The low partition coefficient of imidacloprid indicates that it has no potential to accumulate in biological tissues and further enrichment in the food chain. The occurrence of imidacloprid in the air is determined by its low vapor pressure of 4×10^{-10} Pa which excludes volatilization from treated surfaces. The rapid uptake and translaminar transport of imidacloprid from the treated upper leaf side to the lower surface is excellent, as observed in cabbage leaves (Elbert *et al.*, 1991), and in rice and cucumber (Ishii *et al.*, 1994). However, imidacloprid has a considerable acropetal mobility in xylem of plants. In contrast, its penetration and translocation in cotton leaves was less pronounced, as qualitatively reflected by phosphor-imager autoradiography (Buchholz and Nauen, 2001). This xylem mobility makes imidacloprid especially useful for seed treatment and soil application, but it is equally effective for foliar application (Elbert *et al.*, 1991).

Due to its lack of any acidic hydrogen, the pK_a of imidacloprid is >14, and therefore its transport within the phloem is unlikely, as been shown in several studies (Stein-Dönecke *et al.*, 1992; Tröltzsch *et al.*, 1994). Systemic properties were examined using ^{14}C-labeled imidacloprid. The translocation of imidacloprid in winter wheat and its uptake and translocation from treated cotton seeds into the growing parts of the cotton plant is described by Elbert *et al.* (1998). Registered patterns of use of imidacloprid in agriculture now include traditional foliar spray application as well as soil drench application, drip irrigation, trunk (injection) application, stem or granular treatments and seed treatment.

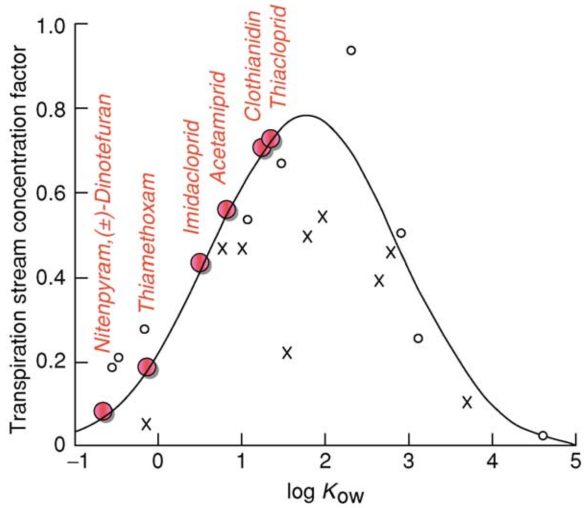

Figure 14 Systemicity of neonicotinoids. Relationship between the translocation of neonicotinoids to barley shoots following uptake by the roots (expressed as the transpiration stream concentration factor), and the octan-1-ol/water partition coefficients (as log K_{ow}). (Diagram and experimental data taken from Briggs, G., Bromilow, R.H., Evans, A.A., **1982**. Relationships between lipophilicity and root uptake and translocation of non-ionized chemicals by barley. *Pestic. Sci. 13*, 495–504). Because of the higher lipophilicity, thiacloprid and clothianidin show the best uptake by the roots from solution, whereas nitenpyram and (±)-dinotefuran are more xylem mobile than the other neonicotinoids.

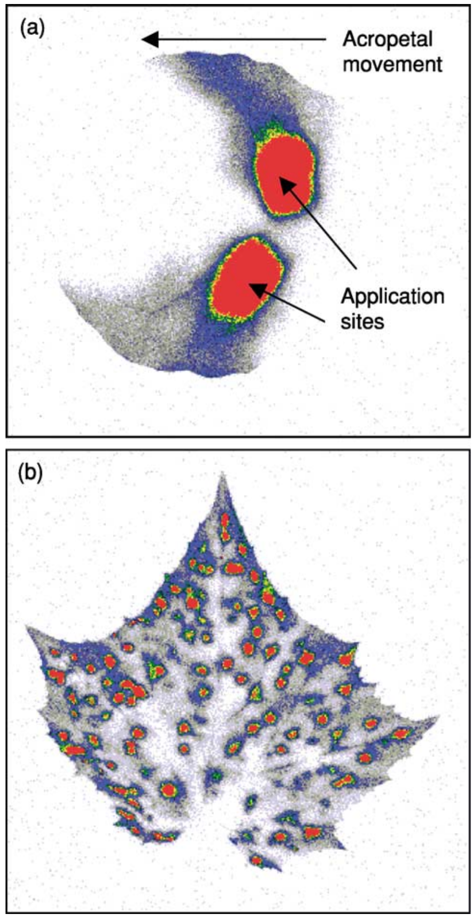

Figure 15 (a) Translocation of [^{14}C]-thiacloprid in cabbage plants 1 day after application of 2 × 5 µl droplets onto the first true leaf. Radioactivity on the surface of the cuticle (residue) was removed by cellulose-acetate stripping; (b) translocation pattern of thiacloprid sprayed to a cucumber leaf.

Because of imidacloprid's systemic properties it is evenly distributed in young, growing plants (Elbert *et al.*, 1991, 1998).

5.3.3.4.1.2. ***Thiacloprid*** It is stable towards hydrolysis even under conditions of heavy rain. Once applied to leaves, thiacloprid shows good rainfastness and photostability, and remains in or on leaves for a considerable time, thus allowing a continous penetration of the active ingredient into the leaf. Its half-life in water at pH 5, 7, and 9 is over 500 h. Photolysis in water (buffered at pH 7) shows a half-life of >100 days. On soil surfaces thiacloprid is also stable under sunlight irradiation (Jeschke *et al.*, 2001). The penetration and translocation behavior of thiacloprid in cabbage was comparable to those reported for imidacloprid (Buchholz and Nauen, 2002). The amounts of thiacloprid stripped off from cabbage application sites were 23% and 17% at 1 day and 7 days after treatment, respectively. Levels in the true leaf increased from 63% to 77% as measured 1 day and 7 days after application, respectively. These results demonstrate that thiacloprid is readily taken up by cabbage leaves, thus providing good systemic control of leaf-sucking pests. The visualization of the translocation pattern of [^{14}C]thiacloprid-equivalents by phosphor-imaging technology revealed xylem mobility, i.e., translocation of the active ingredient in the upwards direction, even 1 day after application to cabbage leaves (**Figure 15a**). This xylem mobility is further highlighted in **Figure 15b**, showing excellent distribution of thiacloprid in cucumber leaves after spray application.

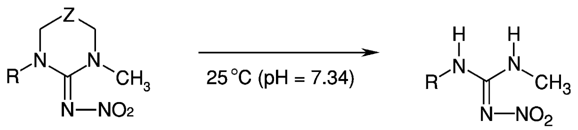
5.3.3.4.1.3. ***Thiamethoxam*** It is a crystalline, odorless compound with a melting point of 139.1 °C. This neonicotinoid has a relatively high water solubility of 4.1 g l^{-1} at 25 °C and a low partition coefficient (log P_{OW} = −0.13 at pH 6.8). In the range of pH 2 to 12 no dissociation is observed (Maienfisch *et al.*, 2001a). These properties favor a rapid and efficient uptake in plants and xylem transport (Widmer *et al.*, 1999) (**Table 3**). Through this systemic activity, all plant parts situated acropetally from the application can be protected (Maienfisch *et al.*, 1999a, 2001a). Thia-

methoxam is hydrolytically very stable at pH 5 with a half-life greater than 1 year at room temperature and stable at pH 7 (estimated half-life at room temperature is 200–300 days) (Maienfisch *et al.*, 2001a). This neonicotinoid is more labile at pH 9, where the half-life is a few days. It is rapidly photolytically degraded with a half-life of about 1 h as a droplet deposit on Teflon. But no decomposition was observed after storage of the active ingredient (a.i.) or formulated product at 54 °C for 2 months; however, at temperatures above 150 °C, exothermic decomposition occurs (Maienfisch *et al.*, 1999a). Under laboratory soils, thiamethoxam degrades at moderate to slow rates. Under field conditions, degradation is generally faster, because of the higher microbial activity of field soils and exposure to light as important degradation pathways (Maienfisch *et al.*, 1999a).

5.3.3.4.1.4. Nitenpyram It is highly soluble in water (840 g l^{-1}), and shows good systemic action (Kashiwada, 1996) and no phytotoxicity, characteristics which enable the various application methods of the neonicotinoid (Akayama and Minamida, 1999). The partition coefficient is low (−0.64) (**Table 3**).

5.3.3.4.1.5. Acetamiprid It is stable in buffer solutions at pH 4, 5, and 7 and under sunlight. It is degraded slowly at pH 9 at 45 °C. Hydrolysis of acetamiprid in 0.5–1 N sodium hydroxide at 90–95 °C for 2 h gave quantitatively *N*-methyl-(6-chloro-pyrid-3-yl)-methylamine (Tokieda *et al.*, 1997). Because of its high solubility in water (**Table 3**), acetamiprid shows a high systemic and translaminar insecticidal activity (Yamada *et al.*, 1999) and is currently used only foliarly.

5.3.3.4.1.6. Clothianidin It has no acidic or alkaline properties at the relevant pH (Stupp and Fahl, 2003). Therefore, the pH of the aqueous system has no influence on its physicochemical properties. It is stable to hydrolysis in a pH range of 4 to 9, but photolysis contributes significantly to its degradation in the environment resulting in an elevated mineralization rate. The water solubility of clothianidin is relatively low (0.327 g l^{-1} at 20 °C) in comparison to the other neonicotinoids that have a nitroguanidyl moiety. This is also reflected by the octanol–water partition coefficient, indicating a favorable adsorption to soil (log P_{OW} = 0.7 at 25 °C) (**Table 3**). On basis of these physicochemical properties no bioaccumulation is expected nor any volatilization, and thus no significant amounts of the substance are to be expected in the atmosphere (Stupp and Fahl, 2003).



5.3.3.5. Proneonicotinoids

Pharmaceutical conceptions in prodrug design generally focus on its potential in overcoming pharmacokinetic problems and poor oral absorption (Testa and Mayer, 2001). Prodrug activation occurs enzymatically, nonenzymatically, or also sequentially (enzymatic step followed by nonenzymatic rearrangement) (Testa and Mayer, 1998). Depending on both the drug and its prodrug, the therapeutic gain may be modest, marked, or even significant (Balant and Doelker, 1995). The field of neonicotinoid chemistry reflects, e.g., with Mannich adducts, some significant examples for useful proneonicotinoids in crop protection (see Sections 5.3.3.5.1 and 5.3.3.5.3).

5.3.3.5.1. Ring cleavage to noncyclic neonicotinoids The six-membered perhydro-1,3,5-thiadiazine (Z = S), hexahydro-1,3,5-triazine (Z = NR), and perhydro-1,3,5-oxadiazine (Z = O) containing neonicotinoids can be prepared by a Mannich type cyclization reaction by treatment, for example, cyclization of the *N*-nitroguanidine moiety with two molar equivalents of formaldehyde (HCHO) in the presence of one or more equivalents of hydrogen sulfide (H_2S), an appropriate amine ($R{-}NH_2$) or water (H_2O) in a suitable solvent. It is known that these cyclic Mannich adducts can cleave into their noncyclic compounds depending on the reaction conditions (pH values). Efficient syntheses of the active ingredient clothianidin, which is readily performed by ring cleavage reaction of the *bis*-aminal structure ($N{-}CH_2{-}N$ bonds) within the 6-ring system of the N,N′-dialkylated 2-(*N*-nitroimino)-hexahydro-1,3,5-triazine, have been previously described (Maienfisch *et al.*, 2000; Jeschke *et al.*, 2003).

The hydrolysis (ring cleavage) of different 6-ring intermediates giving noncyclic neonicotinoids were studied in a physiological salt solution at 25 °C (pH 7.34). It was found that the perhydro-1,3,5-oxadiazines (Z = O) have noteably longer half-lives than the appropriate hexahydro-1,3,5-triazines as *bis*-aminals (Kagabu, 2003a) (**Figure 16**).

Agro Kanesho's hexahydro-1,3,5-triazine (Z = NMe) AKD-1022, a six-membered ring compound, is a proinsecticide of clothianidin (Bryant, 2001). Recently, it was demonstrated that thiamethoxam, having a perhydro-1,3,5-oxadiazine (Z = O) structure, is also an *in vivo*, easy-to-cleave neonicotinoid precursor for the highly active noncyclic neonicotinoid clothianidin (Nauen *et al.*, 2003). This suggests a prodrug principle in the mode of action of thiamethoxam, rather than differences in the binding

site (Kayser *et al.*, 2002). Clothianidin is one of the most prominent metabolites in the leaves of thiamethoxam-treated (soil drench) cotton plants. Thiamethoxam is not only rapidly metabolized in plants but also (within minutes) converted to clothianidin in noctuid larvae. The level of clothianidin detected in the hemolymph is quite high, i.e., physiologically relevant, and considering the electrophysiological results in an interaction with the nAChR in the CNS can be assumed to occur (Nauen *et al.*, 2003). Therefore clothianidin is likely to be responsible for the insecticidal potency of thiamethoxam, and not the parent compound itself, an important fact for resistance management strategies (see Section 5.3.9).

5.3.3.5.2. Mannich adducts as useful precursors The first patent applications covering a number of substituted 5-nitro-tetrahydro-1,3-pyrimidines, the so-called Mannich adducts of certain insecticidally active nitromethylene compounds, were published in 1988 (e.g., compound Bay T 9992, Bayer AG). Due to their potent toxicity to insects and arthropods, numerous different companies produced compounds of this type (Nauen *et al.*, 2001). These Mannich adducts can be prepared via an aminomethylation reaction by the treatment of the CH-acidic nitromethylenes [–N–C(E)=CH–NO_2; E = NHR^2], which react as nitroenamines (Rajappa, 1981), with one or more equivalents of an amine (R^3–NH_2), and at least two molar equivalents of the electrophile formaldehyde (HCHO) in a suitable solvent like alcohols, water, polar aprotic solvents such as tetrahydrofuran, and *N*,*N*-dimethyl-formamide, or solid paraformaldehyde (**Figure 17**; Mannich adduct formation, pathway A). In some cases, a small amount of a strong, nonoxidizing acid, such as hydrochloric acid, can be used as a catalyst. The Mannich adducts have a wide range of substituents R^3 which inhibit the

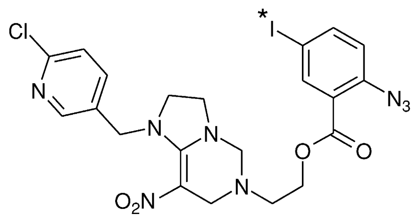

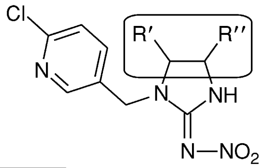

Figure 18 [^{125}I] azidoneonicotinoid (AN) photoaffinity radioligand, a useful probe to explore the structure and diversity of insect nAChRs. (Reproduced from Tomizawa, M., Casida, J.E., **2001**. Structure and diversity of nicotinic acetylcholine receptors. *Pest Mgt Sci.* *57*, 914–922.)

[^{3}H]imidacloprid binding site of *Drosophila* or *Musca* nAChR by 50% at 0.7–24.0 nM (Latli *et al.*, 1997). However, at different pH values, hydrolysis of the Mannich adducts can be observed (**Figure 17**; Mannich adduct cleavage, pathway B).

Application of more stable Mannich adducts in protein biochemistry led to the synthesis of the [^{125}I]azidoneonicotinoid (AN) probe by using 1-(6-chloro-pyrid-3-ylmethyl)-2-nitromethylene-imidazolidine (NTN32692) as the photoaffinity radioligand (Latli *et al.*, 1997; Maienfisch *et al.*, 2003) (**Figure 18**). This probe facilitated the identification of insecticide-binding site(s) in insect nAChRs.

In the first photoaffinity labeling of an insect neurotransmitter receptor, [^{125}I]AN exhibited high

affinity (8 nM), and successfully identified a 66 kDa polypeptide in *Drosophila* head membranes. Several cholinergic ligands and neonicotinoid insecticides, like imidacloprid and acetamiprid, strongly inhibited this photoaffinity labeling. Thus, the labeled polypeptide is pharmacologically consistent with the ligand- and insecticide-binding subunit of *Drosophila* nAChR (Tomizawa and Casida, 1997, 2001).

5.3.3.5.3. Active metabolites of neonicotinoids From the metabolic pathway (see Section 5.3.7.1) of imidacloprid it is known that hydroxylation of the imidazolidine ring leads in general to the mono- (R′ = —H; R″ = —OH) and the bishydroxylated (R′, R″ = —OH) derivatives, both of which have reduced affinity (**Figure 19**). Alternatively, the mono (R′ = —OH; R″ = —H) derivative reflects a higher level of efficacy (pI_{50} value 8.5) (Nauen *et al.*, 2001; Sarkar *et al.*, 2001). Interestingly, the olefin metabolite showed a higher pI_{50} value for nAChR from housefly head membranes than imidacloprid, and provides superior toxicity to some homopterans after oral ingestion (Nauen *et al.*, 1998b, 1999b). This result suggests that for the central ring system the exact rearrangement of the ring atoms, and not the electronic effect of the ring system, seems to be necessary for insecticidal activity. A similar phenomenon has been described for the conjugated pyridone derivatives (Kagabu, 1999).

5.3.4. Biological Activity and Agricultural Uses

The biological activity and agricultural uses of neonicotinoid insecticides are enormous' and these insecticides are continuing to see new uses (Elbert and Nauen, 2004). It is definitely beyond the scope of this chapter to provide a full overview of the agronomic and horticultural cropping systems that use neonicotinoid insecticides and readers interested in these aspects should refer to many articles and book chapters published during the past decade, e.g., Elbert *et al.* (1991, 1998), Yamamoto (1999), Kiriyama and Nishimura (2002), and Elbert and Nauen (2004). In order to provide a flavor of the agricultural uses of neonicotinoids, and the affected target pests, a few examples considering imidacloprid are given below. Imidacloprid is presently the most widely used neonicotinoid insecticide worldwide.

5.3.4.1. Efficacy on Target Pests

Due to their unique properties – high intrinsic acute and residual activity against sucking and some chewing insect species, high efficacy against aphids, whiteflies, leafhoppers and planthoppers, and the Colorado potato beetle, and excellent acropetal translocation – neonicotinoids can be used in a variety of crops (**Figure 20**). These uses include: aphids on vegetables, sugar beet, cotton, pome fruit, cereals, and tobacco; leafhoppers, planthoppers, and water weevil on rice; whiteflies on vegetables, cotton, and citrus; lepidopteran leafminer on pome fruit and citrus; and wireworms on sugar beet and corn (**Table 4**). Termites and turf pests such as white grubs can also be controlled by imidacloprid (Elbert *et al.*, 1990, 1991).

Neonicotinoids such as imidacloprid and thiamethoxam also control important vectors of virus diseases, thereby impairing the secondary spread of viruses in various crops. This control has been observed, e.g., for the persistent barley yellow dwarf virus (BYDV) transmitted by *Rhopalosiphum padi* and *Sitobion avenae* (Knaust and Poehling, 1992). Seed treatments proved highly effective in controlling barley yellow dwarfvirus vectors and the subsequent infection, in a series of field trials in southern England. Sugar beet seed, pelleted with imidacloprid, was well protected especially against infections with beet mild yellow virus transmitted by the peach potato aphid, *Myzus persicae* (Dewar and Read, 1990).

Spodoptera frugiperda	Second instar	200

5.3.4.2. Agricultural Uses

Due to their high systemicity, diverse ways of application are feasible and these methods have been introduced into practice. Soil treatments can be done by incorporation of granules, injection, application with irrigation water, spraying, and use of tablets. Plants or plant parts can be treated by seed dressing, pelleting, implantation, dipping, injection, and painting. These methods have led to a more economic and environmentally friendly use of these products, fitting well into various integrated pest management (IPM) programmes. In this section, imidacloprid has been chosen as an example of a neonicotinoid, and a few examples of its use in various crops is given. Such uses include treatments for rice in Japan, cotton in the mid-south of the USA, vegetables in Mexico, and cereals in France. In these crops the neonicotinoid insecticides targets mainly early-season pests.

5.3.4.2.1. Rice In Japan, nursery box application of insecticides is a standard procedure, and it is currently used in 50% of the rice-growing area. This type of treatment is directed against early-season pests like *Lissorhoptrus oryzophilus* (rice water weevil) and *Lema oryzae* (rice leaf beetle). In contrast to commercially available products like carbosulfan, benfuracarb, and propoxur, which control mainly rice water weevil and rice leaf beetle, imidacloprid covers the whole spectrum of early-season

pests including *N. cincticeps* (green rice leafhopper), *Laodelphax striatellus* (smaller brown planthopper), and also mid- and late-season hopper species, like *Sogatella furcifera* (white-backed planthopper) and *Nilaparvata lugens* (brown planthopper). Benefits of such nursery box applications include, reduced labor input, longer residual effect, and reduced side effects against nontarget organisms when compared to surface treatments.

Based on 5-year field trials, a use pattern for imidacloprid against the main rice pests has been established. When applied as a granule, 2 granular GR with 1 g a.i. per nursery box (= 200 g a.i. ha^{-1}) 0–3 days before transplanting, the product gives full protection for 50–90 days against different hoppers species. By controlling *L. striatellus,* a 91% reduction of the rice stripe virus was observed. An excellent residual effect was detected up to 50 days after transplanting against *L. oryzophilus*, and up to 60 days against *L. oryzae*.

Apart from the seedling box application, imidacloprid can be used as a granule for water surface application, as a wettable powder (WP) or as a dust formulation for foliar treatment, and also as a seed dressing to control the above mentioned pests on rice. Under field conditions of such use, no apparent effects from imidacloprid treatments were observed against populations of the spiders *Pardosa pseudoannulata* and *Tetragnatha vermiformis*.

Therefore, imidacloprid can be regarded very effective against rice insects and flexible to use, but it is most efficient in nursery box application. It outperforms other conventional insecticides due to its broader efficacy and lower dose rates. Virus diseases are suppressed through effective vector control, and low toxicity has been observed against important beneficials in rice.

5.3.4.2.2. Cotton The main cotton pests in the mid South of the USA are *Thrips tabaci, Lygus lineolaris* (tarnished plant bug), *Neurocolpus nubilis* (clouded plant bug), *Anthonomus grandis* (boll weevil), *Heliothis virescens* (tobacco budworm), and *Helicoverpa zea* (bollworm). Other pests such as *Pseudatomoscelis seriatus* (cotton fleahopper), *Aphis gossypii* (cotton aphid), *Spodoptera exigua* (beet armyworm) and *S. frugiperda* (fall armyworm) are of lesser importance in this region.

Thrips tabaci attacks the terminal bud and two to four true leaves. The plant is damaged by a reduced stand, retarding growth, killed buds, and delayed fruiting, with significant yield reduction. *Lygus lineolaris* damages by feeding on pinhead squares, which causes young squares to shed. Terminal bud injury leads to multiple branched plants ("crazy cotton"). Symptoms caused by *N. nubilis* are similar to those of *L. lineolaris*.

It is thus evident that damage caused by early-season pests, such as thrips and bugs, can be very important. Loss of first-position squares can have detrimental effects on the yield potential of the plant. If normal fruiting of cotton plants is prevented, this can cause a delay in maturity, which in turn necessitates additional late-season insecticidal applications to control bollworms, tobacco budworms, and boll weevils.

A 480 FS formulation (Gaucho®) is applied for seed dressing, against early infestations of thrips and aphids, at 250 g a.i. per 100 kg cotton seed (37 g a.i. ha^{-1}). Against bugs and later attack of aphids, three foliar split applications at low dose rates are recommended (Provado® 1.6 F, 3 × 15 g a.i. ha^{-1} (Table 4). These should be done as band sprays at intervals of 7–10 days. The first application starts 30 days after emergence of the five leaf stage, subsequent to the Gaucho® protection period. The *Heliothis–Helicoverpa* complex is controlled by conventional insecticides in mid-season, whereas boll weevil and armyworms are controlled by azinphos-methyl or cyfluthrin, respectively.

5.3.4.2.3. Vegetables Virus diseases have been the main factors affecting the tomato and chilli production in Mexico during the past 20 years, and these diseases have led to significant yield reductions in many regions. These crops are grown on approximately 160 000 ha with constant virus infestation in 30–35% of the fields, with persistent viruses being the most important in Mexican agriculture. In tomato crops, viruses can infest up to 100% of the crop. The damage depends on the type of virus, the population density of vectors, and the developmental stage of the crop. Protection by conventional insecticide treatments under plastic covered greenhouses, however, has not given satisfactory results (Elbert and Nauen, 2004).

5.3.4.2.4. Cereals The traditional method in controlling virus vectors in Europe is regular monitoring of aphid attack of young wheat and barley plants after emergence in autumn. If the threshold of 10% infested plants with at least one aphid per plant has been surpassed, usually a pyrethroid will be sprayed. Monitoring has to be continued, because the residual effect of the treatment may be insufficient for vector control. Depending on climatic conditions and the duration of the aphid attack, a second or a third application may be required. This rather time consuming and difficult procedure can be avoided by a seed treatment with imidacloprid.

Barley yellow dwarf virus vectors such as *R. padi* and *S. avenae* are controlled and the secondary spread of the disease is inhibited. In contrast to one or several sprays, seed dressing as the only treatment assures prolonged protection during the critical period, when virus transmission is of importance. Furthermore pyrethroid sprays with a broad spectrum of activity can be substituted by only one application of imidacloprid, which has virtually no effects on beneficials and other nontarget organisms. High yield varieties achieve their optimum yield potential only if they are sown early, which implies an enhanced risk of infestation with aphids and, consequently, with barley yellow dwarf virus. As Gaucho® controls aphids and suppresses the infection with this virus, early-sown cereals are especially well protected against insects and diseases. Therefore, a better tillering is achieved and 15–25% of the seed can be saved.

Both imidacloprid seed treatment and pyrethroid spray application have very good to excellent effects against the vector *R. padi*. The acute effect of the pyrethroid was better due to its quick knockdown activity. Imidacloprid alternatively acts more slowly, so, it takes more time to kill invading aphids, but its residual effect is much more pronounced. Thus imidacloprid use results in long-lasting control of aphids and, as a consequence, considerably better prevention of virus symptoms. A yield increase of 26% over untreated controls was achieved in comparison with, 10% achieved by pyrethroid treatment.

Field trials over 4 years in France confirmed that both wheat and barley are well protected against the above-mentioned pests and diseases. In an average of 76 trials in wheat and 66 trials in barley a yield increase of 3.1 dt ha^{-1} and 4.4 dt ha^{-1}, respectively; was obtained with the Gaucho® treatment when compared with untreated.

5.3.4.3. Foliar Application

Spray applications are especially used against pests attacking crops such as cereals, maize, rice, potatoes, vegetables, sugar beet, cotton, and deciduous trees. Table 4 shows the acute activity (estimated LC_{95} (lethal concentration at which 95% of insects are killed) in ppm a.i.) of imidacloprid against a variety of pests, following foliar application (dip and spray treatment) of host plants under laboratory and greenhouse conditions. Imidacloprid was very active to a wide range of aphids. The most susceptible was the damson hop aphid *Phorodon humuli* (LC_{95} 0.32 ppm), which is often highly resistant against conventional insecticides (Weichel and Nauen, 2003). Imidacloprid was highly effective against some of the most important rice pests, such as leafhoppers and planthoppers, rice leaf beetle *L. oryzae* and rice water weevil *L. oryzophilus*. Although imidacloprid is generally less effective against biting insects, its efficacy against the Colorado potato beetle *Leptinotarsa decemlineata* is relatively high (LC_{95} 40 ppm). The LC_{95} values for the second or third instar larvae of some of the most deleterious noctuid pest species of the order Lepidoptera, *Helicoverpa armigera, Spodoptera frugiperda*, and *Plutella xylostella*, were approximately 200 ppm, and higher than those for the species mentioned above (Elbert *et al*., 1991).

5.3.4.4. Soil Application and Seed Treatment

Typical soil insect pests such as *Agriotes* sp., *Diabrotica balteata*, or *Hylemyia antiqua* were controlled by incorporation of 2.5–5 ppm a.i. into the soil. Higher concentrations of imidacloprid are necessary to control *Reticulitermes flavipes* (7 ppm) and *Agrotis segetum* (20 ppm). However, imidacloprid activity is much more pronounced against early-season sucking pests, which attack the aerial parts of a wide range of crops. Soil concentrations as low as 0.15 ppm a.i. gave excellent control of *Myzus persicae* and *Aphis fabae* on cabbage in greenhouse experiments (Elbert *et al*., 1991). A good residual activity is essential for the protection of young plants.

5.3.5. Mode of Action

The biochemical mode of action of neonicotinoid insecticides has been studied and characterized extensively in the past 10 years. They act selectively on insect nAChRs, a family of ligand-gated ion channels located in the CNS of insects and responsible for rapid neurotransmission. The nAChR is a pentameric transmembrane complex, and each subunit consists of an extracellular domain containing the ligand binding site and four transmembrane domains (Nauen *et al*., 2001; Tomizawa and Casida, 2003). Neonicotinoid insecticides bind to the acetylcholine binding site located on the hydrophilic extracellular domain of α-subunits. Their ability to displace tritiated imidacloprid from its binding site correlates well with their insecticidal efficacy (Liu and Casida, 1993a; Liu *et al*., 1993b). [^{3}H]imidacloprid binds with nanomolar affinity to nAChR preparations from insect tissues, and next to the less specific α-bungarotoxin, it is the preferred compound in radioligand competition studies (Lind *et al*., 1998; Nauen *et al*., 2001). Furthermore, electrophysiological studies revealed that neonicotinoid insecticides act agonistically on nAChR, and this interaction is again very well correlated with

their potential to control target pest species. In contrast antagonistic compounds of mammalian nAChR were shown to be far less active as insecticides (Nauen *et al.*, 1999a). All neonicotinoid insecticides act with nanomolar affinity against housefly and other insect nAChRs, except thiamethoxam, which exhibits a comparatively low affinity for the [^{3}H]imidacloprid binding site. This low affinites was attributed to its proneonicotinoid nature (see Sections 5.3.3.5 and 5.3.3.5.1), as it was shown to be activated to clothianidin in insects and plants (Nauen *et al.*, 2003).

The mode of action of neonicotinoid insecticides has been described in several excellent reviews which should serve as a primary source for further informations (Kagabu, 1997a; Matsuda *et al.*, 2001; Nauen *et al.*, 2001; Tomizawa and Casida, 2003). These reviews describe our current knowledge of the structure and function of insect nAChR, characterized by receptor binding studies, phylogenetic considerations regarding receptor homologies between orthologs from different animal species, and electrophysiological investigations, as well as the description of a vast range of a structurally diverse receptor ligands, of course with an emphasis on neonicotinoid insecticides.

5.3.6. Interactions of Neonicotinoids with the Nicotinic Acetylcholine Receptor

5.3.6.1. Selectivity for Insect over Vertebrate nAChRs

Electrophysiological measurements reported in numerous studies have revealed that nAChRs are widely expressed in the insect nervous system on both postsynaptic and presynaptic nerve terminals, on the cell bodies of interneurons, motor neurons, and sensory neurons (Goodman and Spitzer, 1980; Harrow and Sattelle, 1983; Sattelle *et al.*, 1983; Breer, 1988; Restifo and White, 1990). Schröder and Flattum (1984) using extracellular electrophysiological recordings were the first to identify that the site of action of the nitromethylene nithiazine was on the cholinergic synapse. A number of subsequent electrophysiological and biochemical binding studies revealed that the primary target of the neonicotinoids were the nAChRs (Benson, 1989; Sattelle *et al.*, 1989; Bai *et al.*, 1991; Leech *et al.*, 1991; Cheung *et al.*, 1992; Tomizawa and Yamamoto, 1992, 1993; Zwart *et al.*, 1992; Liu and Casida, 1993a; Tomizawa *et al.*, 1996). Recent electrophysiological studies indicate that imidacloprid acts as an agonist on two distinct nAChR subtypes on cultured cockroach dorsal unpaired motoneuron (DUM) neurons (Buckingham *et al.*, 1997), an α-bungarotoxin (α-BGTx) sensitive nAChR with "mixed" nicotinic/muscarinic pharmacology and an α-BGTx insensitive nAChR. Such electrophysiological observations were supported by binding studies with [^{3}H]imidacloprid in membrane preparations from *M. persicae*. These ligand competition studies revealed the presence of high and low-affinity nAChR binding sites for imidacloprid in *M. persicae* (Lind *et al.*, 1998).

The identification of multiple putative nAChR subunits by molecular cloning is consistent with a substantial diversity of insect nAChRs (Gundelfinger, 1992). At present, at least five different subunits have been cloned from *Drosophila melanogaster* (Schulz *et al.*, 1998), from the locust *Locusta migratoria* (Hermsen *et al.*, 1998), and from the aphid *M. persicae* (Huang *et al.*, 1999). Despite the considerable number of subunits identified, only a few functional receptors were obtained after expression of different subunit combinations in *Xenopus* oocytes or cell lines. Initial work suggested that some subunits can form homooligomeric functional receptors when expressed in *Xenopus* oocytes. This was shown for Lα1 from the locust *Schistocerca gregaria* (Marshall *et al.*, 1990; Amar *et al.*, 1995), and for the Mpα1 and Mpα2 from *M. persicae* (Sgard *et al.*, 1998). However, the expression of these subunits was not very effective and generated only small inward currents (5–50 nA) following application of nicotine or acetylcholine. Alternatively, all three *Drosophila* α subunits (ALS, SAD, and Dα2) can form functional receptors in *Xenopus* oocytes when coexpressed with a chicken neuronal β2 subunit (Bertrand *et al.*, 1994; Matsuda *et al.*, 1998; Schulz *et al.*, 1998), suggesting that additional insect nAChR subunits remain to be cloned. Radioligand binding studies using several *M. persicae* α subunits coexpressed with a rat β2 subunit in the *Drosophila* S2 cell line also indicate pharmacological diversity in *M. persicae* (Huang *et al.*, 1999). In these binding studies it was shown that imidacloprid selective targets were formed by Mpα2 and Mpα3, but not Mpα1 subunits. These examples indicate that our understanding of the complexity of insect nAChR is still limited, and that electrophysiology will play an essential role in determining the significance of certain subunit combinations in the mode of action of neonicotinoid and other insecticidally active ligands.

5.3.6.2. Whole Cell Voltage Clamp of Native Neuron Preparations

The use of isolated neurons from insect CNS for electrophysiological studies is a suitable tool to

investigate the mode of action of new insecticidal compounds, which act on a range of neuronal target sites. Primary neuronal cell cultures from *H. virescens* larvae, one of the most important lepidopteran pest species, is one of these suitable tools. *H. virescens* neurons respond to the application of ACh, with a fast inward current of up to 5 nA at a holding potential of −70 mV. The current reversed at a holding potential close to 0 mV, indicating the activation of nonspecific cation channels, i.e., nAChRs.

Figure 21 illustrates the whole cell currents elicited by application of 1 μM nithiazine and the second generation neonicotinoids, acetamiprid, nitenpyram, and clothianidin. All of these compounds act as agonists on the nAChR, but the potency and agonistic efficacy of each of these compounds were quite different. Imidacloprid and clothianidin were the most potent compounds in this *Heliothis* preparation with an EC_{50} of 0.3 μM (Table 5). In the case of imidacloprid there was good agreement with electrophysiological measurements

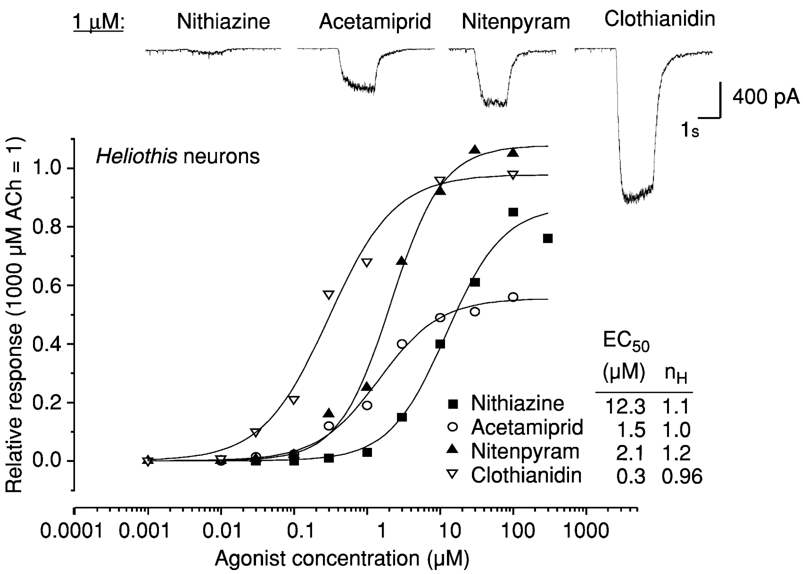

Figure 21 Whole cell current responses of a neuron isolated from the CNS of *Heliothis virescens* after application of different neonicotiniods. The dose-response curve was fitted by the Hill equation. All currents were first normalized to mean amplitudes elicited by 10 μM ACh before and after each test concentration was applied, and then normalized to the relative amplitude elicited by 1000 μM ACh. EC_{50} values given correspond to the half maximal activation of nAChR by each agonist. The Hill coefficient (n_H) of all tested compounds was close to 1. The upper inset shows the corresponding responses for the neonicotinoids at 1 μM (holding potential −70 mV). All currents were obtained from the very same neuron. (Reproduced with permission from Nauen, R., Ebbinghaus-Kintscher, A., Elbert, A., Jeschke, P., Tietjen, K., **2001**. Acetylcholine receptors as sites for developing neonicotinoid insecticides. In: Iishaaya, I. (Ed.), Biochemical Sites of Insecticide Action and Resistance. Springer, New York, pp. 77–105.)

Table 5 Comparison between electrophysiological and [^{3}H]imidacloprid displacement potencies for different neonicotinoids and epibatidine on insect nAChRs. Electrophysiological data (EC_{50} and relative (agonist) efficacy) were obtained from neuron cell bodies isolated from the CNS of *Heliothis virescens.* EC_{50} and relative efficacy values represent the mean of n separate experiments on different neurons. The inhibition of [^{3}H]imidacloprid binding to nAChR in housefly head membrane preparations by the compounds is expressed as pI_{50} value (pI_{50} values (= −log M) correspond to the concentration of cold ligand displacing 50% of bound [^{3}H]imidacloprid from housefly head membranes)

Compound	*n*	*EC_{50} (μM ± SD)*	*Relative efficacy (1 mM ACh = 1)*	*[^{3}H]imidacloprid pI_{50}*
Imidacloprid	4	0.31 ± 0.15	0.14 ± 0.02	9.3
Clothianidin	3	0.33 ± 0.03	0.99 ± 0.08	9.2
Acetamiprid	3	1.07 ± 0.37	0.56 ± 0.05	8.7
Nitenpyram	3	1.66 ± 0.38	0.98 ± 0.07	8.6
(±)-Epibatidine	3	1.69 ± 0.79	0.20 ± 0.05	6.2
Nithiazine	4	9.60 ± 3.20	0.79 ± 0.06	6.8

recorded from isolated cockroach neurons, where imidacloprid exhibited an EC_{50} of 0.36 μM (Orr *et al.*, 1997). Acetamiprid, nitenpyram, and the natural toxin epibatidine exhibited an EC_{50} of between 1 and 2 μM (**Table 5**). Similar values were also observed for the cockroach preparation, with an EC_{50} between 0.5 and 0.7 μM for epibatidine and acetamiprid (Orr *et al.*, 1997). Nithiazine had the lowest potency, with an EC_{50} of about 10 μM. The neonicotinoids, clothianidin, and nitenpyram were full agonists, whereas acetamiprid, epibatidine, and imidacloprid were partial agonists. The maximal response elicited by saturable concentrations of imidacloprid (100 μM) was only 15% of the maximal current obtained by 1000 μM ACh. In earlier work on isolated cockroach neurons (Orr *et al.*, 1997) and isolated locust neurons (Nauen *et al.*, 1999b), it was also found that imidacloprid acted as a partial agonist on insect nAChRs. The partial agonistic action of imidacloprid was also observed with chicken α4β2 nAChRs, and on a hybrid nAChR formed by the coexpression of a *Drosophila* α subunit (SAD) with the chicken β2 subunit in *Xenopus* oocytes (Matsuda *et al.*, 1998). Imidacloprid activates very small inward currents in clonal rat phaeochromocytoma (PC 12) cells, thus also indicating partial agonistic actions (Nagata *et al.*, 1996).

Furthermore, single-cell analysis revealed that imidacloprid activates predominatly a subconductance of approximately 10 pS, whereas acetylcholine activated mostly the high conductance state with 25 pS. Multiple conductance states were also observed in an insect nAChR reconstituted into planar lipid bilayers (Hancke and Breer, 1986) and on locust neurons (van den Breukel *et al.*, 1998).

5.3.6.3. Correlation between Electrophysiology and Radioligand Binding Studies

There is a good correlation between electrophysiological measurements, using isolated *Heliothis* neurons, and radioligand binding studies on housefly head membranes regarding the affinity of different ligands to nAChRs (**Figure 22**). This good correlation for the neonicotinoids may indicate that houseflies (binding data) and tobacco budworms (electrophysiology) have similar binding sites for imidacloprid and related compounds. Biochemical investigations using [^{3}H]imidacloprid as a radioligand in a number of different insect membrane preparations, e.g., from *Periplaneta americana*, *Lucilia sericata*, *D. melanogaster*, *Manduca sexta*, *H. virescens*, *Ctenocephalides felis*, *M. persicae*, and *N. cincticeps*, indicate that many (if not all) insects have high specific imidacloprid binding sites with nearly identical K_d values of ~1–10 nM (Lind *et al.*, 1998). However, it was also found that only the homopteran species seems to have an additional very high affinity binding site.

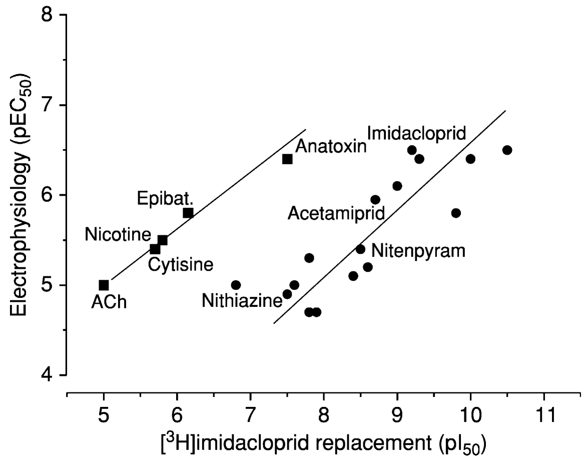

Figure 22 Comparison between electrophysiological and binding potencies of different neonicotinoids and nicotinoids. Electrophysiological data were obtained from neuron cell bodies isolated from the CNS of *Heliothis virescens*. pEC_{50} values (= −log *M*) correspond to the half maximal activation of nAChR by each agonist. Binding data: pI_{50} values (= −log *M*) correspond to the concentration of cold ligand displacing 50% of bound [^{3}H]imidacloprid from housefly head membranes. (Reproduced from Nauen, R., Ebbinghaus-Kintscher, A., Elbert, A., Jeschke, P., Tietjen, K., **2001**. Acetylcholine receptors as sites for developing neonicotinoid insecticides. In: Iishaaya, I. (Ed.), Biochemical Sites of Insecticide Action and Resistance. Springer, New York, pp. 77–105.)

In general, the pI_{50} values obtained by the displacement of specifically bound [^{3}H]imidacloprid from housefly head membranes were two to four orders of magnitude higher than the electrophysiologically determined pEC_{50} values obtained from isolated *Heliothis* neurons. Similar differences in biochemical binding and functional assay studies were also observed for different vertebrate nAChRs (review: Holladay *et al.*, 1997). A possible explanation for this phenomenon might be provided by considering the following: it is generally accepted that each nAChR can exist in multiple states, i.e., a resting state, an active (open) state, and one or more desensitized state(s), each of which has different affinities for ligands. The active state has a low affinity for ACh (K_d ranging from about 10 μM to 1000 μM), whereas the desensitized state(s) has a higher affinity (K_d ranging from about 10 nM to 1 μM) for nicotinic ligands (Lena and Changeux, 1993).

The kinetics of the transitions between these states have been resolved for *Torpedo* nAChR *in vitro*. The rate of isomerization between the resting and active state lies in the μs to ms timescale, and

within the desensitized state over a timeframe of seconds to minutes (Changeux, 1990, cited in Lena and Changeux, 1993). Because binding studies are conducted over a timescale of minutes to hours they may reflect interaction with the desensitized state(s), whereas electrophysiological studies measure the interaction of ligands with the active state. Considering this, it is surprising that there is a direct correlation between electrophysiological and biochemical binding studies for natural alkaloids such as (−)-nicotine, cytisine, (±)-epibatidine and anatoxin A (**Figure 22**). For these compounds the pI_{50} and pEC_{50} values were in the same range, with a good correlation. It is a general observation that natural alkaloids such as nicotine and epibatidine exhibit an agonistic potency in electrophysiological assays on isolated cockroach neurons (Bai *et al.*, 1991; Buckingham *et al.*, 1997; Orr *et al.*, 1997), *Heliothis* neurons (**Figure 22**), and locust neurons (Nauen *et al.*, 1999b) (see below). This potency is comparable to highly insecticidal neonicotinoids like imidacloprid. Matsuda *et al.* (1998), using a hybrid receptor formed by the coexpression of the *Drosophila* α subunit SAD with the chicken ß2 observed a comparable agonistic potency for both (−)-nicotine and imidacloprid. However, the agonistic potency of (+)-epibatidine was about two orders of magnitude greater. In contrast, all binding studies using [^{3}H]imidacloprid on housefly head membranes (Liu and Casida, 1993a, 1993b; Liu *et al.*, 1995; Wollweber and Tietjen, 1999), whitefly preparations (Chao *et al.*, 1997; Nauen *et al.*, 2002; Rauch and Nauen, 2003), and *Myzus* preparations (Nauen *et al.*, 1996, 1998a; Lind *et al.*, 1998), indicate that imidacloprid has a considerably higher potency in replacing specifically bound [^{3}H]imidacloprid than (−)-nicotine.

5.3.7. Pharmacokinetics and Metabolism

Neonicotinoids have moderate and different water solubility. They are nonionized and not readily hydrolyzed at physiological pH values (**Table 3**). The substances are biodegradable, therefore no accumulation was observed in mammals or through food chains (Roberts and Hutson, 1999). Neonicotinoid metabolism involves mostly detoxification reactions evident in three pathways (Tomizawa and Casida, 2003): (1) the brief period for poisoning at sublethal doses in both insects and mammals, (2) the synergistic effects of detoxification inhibitors on insecticidal action, and (3) the potency of metabolites relative to the parent compounds on nAChRs. The pharmacokinetics of neonicotinoids and imidacloprid have been investigated in *S. littoralis*, and the obtained profiles were consistent with high metabolism and an important role of nontarget tissues as sinks in this less responsive species (Greenwood *et al.*, 2002).

5.3.7.1. Metabolic Pathways of Commercial Neonicotinoids

5.3.7.1.1. Imidacloprid The metabolism of imidacloprid is strongly influenced by the method of application (Nauen *et al.*, 1998b). Depending on time and plant species, imidacloprid is degraded more or less completely, as comparative studies in many field crops have revealed (Araki *et al.*, 1994). The uptake and translocation of [^{14}C]imidacloprid after foliar application was studied in cotton. These studies showed that imidacloprid is taken up readily when mixed with the adjuvant Silwet L-77, then translocated acropetally and rapidly metabolized (Nauen *et al.*, 1999b). Experiments with seed-treated cotton plants revealed that only 5% of the applied imidacloprid was taken up by the young plant, and that 27 days after sowing, approximately 95% of the parent compound was metabolized (Tröltzsch *et al.*, 1994).

From results of soil metabolism studies it was found that imidacloprid is completely degradable and will not persist in soil. Under standard laboratory conditions the aerobic degradation of imidacloprid has a half-life (DT_{50}) of 156 days. The a.i. is degraded to carbon dioxide, and any residues are firmly bound to the soil matrix (Krohn and Hellpointer, 2002). Radioactively labeled imidacloprid shows that other degradation products, >10% of the applied radioactivity, do not occur. Sunlight and anaerobic conditions accelerated the degradation of imidacloprid. The degradation pathway shows that the neonicotinoid itself, and not the individual degradation products of the parent compound, is present in soil (Krohn and Hellpointer, 2002). Imidacloprid is not stabile in an aqueous environment, and in such an environment sunlight further accelerates the degradation.

The metabolism of imidacloprid was studied in tomatoes, potatoes, and maize (Roberts and Hutson, 1999) (**Figure 23**). In experiments using tomatoes, [^{14}C-*pyridinyl*]imidacloprid was applied to fruits. The main metabolites were the *N*-desnitro-imidacloprid and the 4- and 5-hydroxy derivatives (see Section 5.3.3.5.3). Small amounts of the cyclic urea, the *N*-nitroso compound were identified. A similar pattern of metabolites to the above mentioned was described for vines, together with a trace of the bicyclic triazinone. Traces of parent imidacloprid

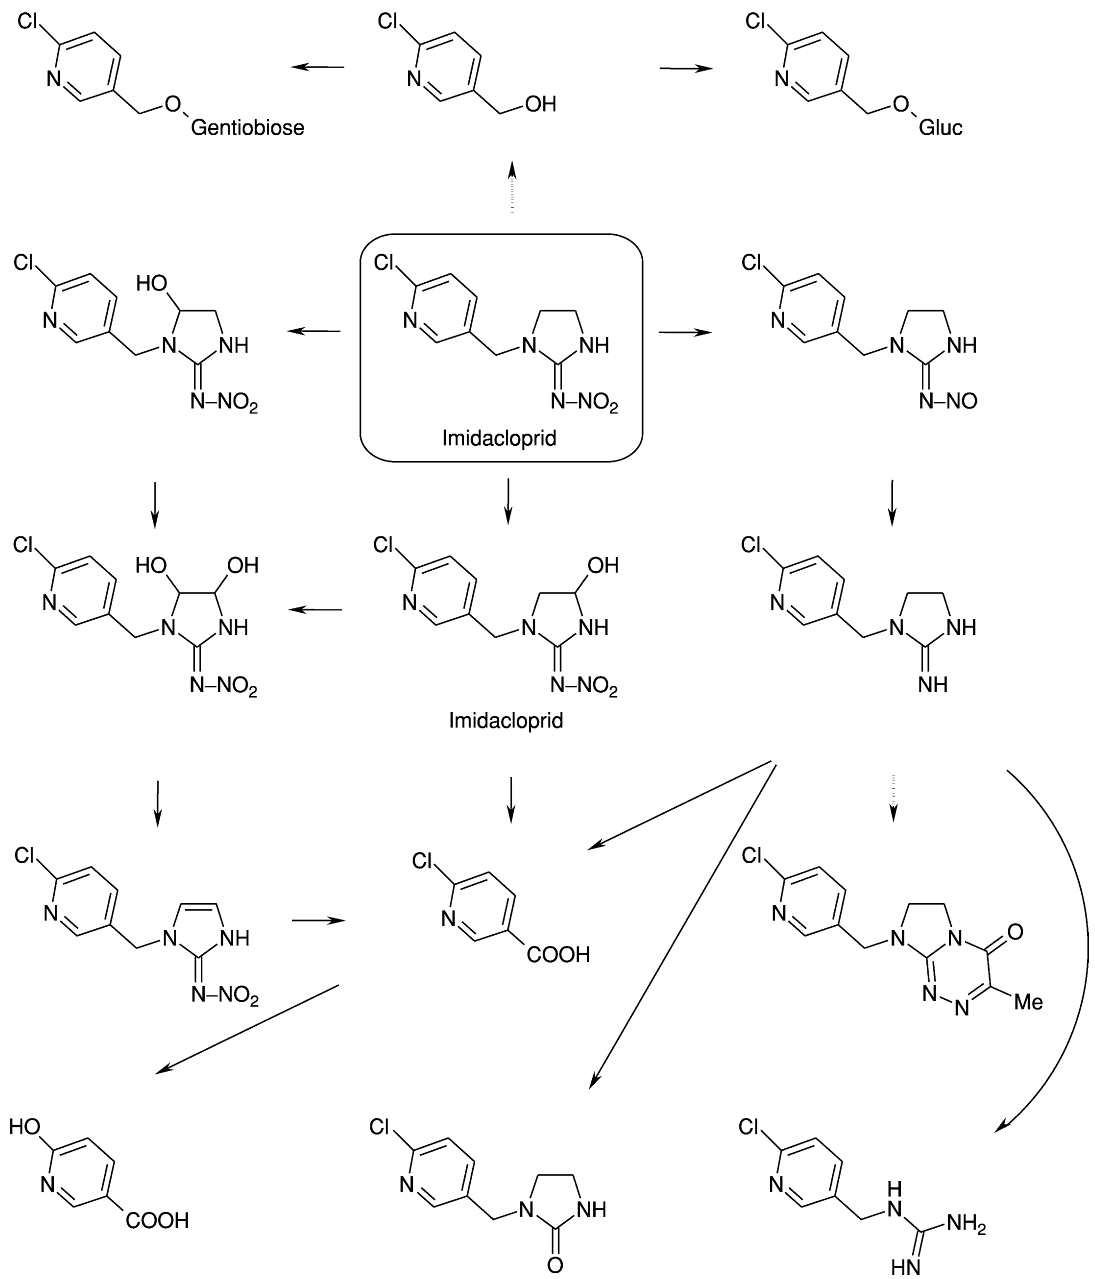

Figure 23 Proposed pathway of imidacloprid metabolism in plants. (Reproduced with permission from Roberts, T.R., Hutson, D.H. (Eds.), **1999**. Metabolic Pathways of Agrochemicals, Part 2, Insecticides and Fungicides. Cambridge University Press, Cambridge.)

and 6-chloro-nicotinic acid (6-CNA) were detected in the tubers. Koester (1992) studied the comparative metabolism of imidacloprid in suspension cultures of cells of several plant species including soybean and cotton, and found that the initial pathway of degradation proceeded mainly by monohydroxylation of the imidazolidine ring and dehydration to the olefin (see Section 5.3.3.5.3). Small amounts of 6-CNA and the 6-chloro-picolyl alcohol (6-CPA) and its glucopyranosid were formed. These identified metabolites are consistent with those found in whole plants.

5.3.7.1.2. Thiacloprid The metabolic pathway of the systemic thiacloprid, in quantitative and also qualitative terms, is similar in all crops (fruiting crops, cotton) investigated (Klein, 2001). The parent compound labeled in [methylene-^{14}C]-position is always the major component. The presence of high amounts of 6-CNA in cotton seed is due to

the accumulation of this acid in the seed as a phloem sink, after being secreted from the apoplasm into the phloem as a trap compartment for weak acids (Klein, 2001). It originated from leaf metabolism, where it was also detected (Klein, 2001). All main metabolites identified in plants were also detected in the rat and livestock metabolism study. By using two different labeling positions ([methylene-^{14}C] and [thiazolidine-^{14}C]), besides the unchanged parent compound, 25 metabolites were isolated and identified in the rat excreta. In goats and hens the residue levels in tissues and organs, as well as in milk and eggs, were low due to the fast elimination. There was no bioaccumulation of residues in any of the tissues. Generally, the metabolism of thiacloprid proceeded via the following pathways (Klein, 2001):

- hydroxylation of the parent compound at the 4-position of 1,3-thiazolidine ring and oxidative cleavage at the methylene bridge leading to 6-CPA and 6-CNA followed by conjugation of these two aglycones with sugars
- the corresponding 1,3-thiazolidine ring metabolites mainly comprised of the free 1,3-thiazolidine, the 4-hydroxylated 1,3-thiazolidine and its 4,5-dehydro (olefinic) derivative, as well as conjugates
- the *N*-nitrile moiety was hydrolyzed to the corresponding *N*-amide derivative, which was then *N*-hydroxylated
- the 1,3-thiazolidine ring system was cleaved in 1-position and the sulfur oxidized or methylated, forming the sulfonic acid or the *S*-methy-sulfoxyl and *S*-methyl-sulfonyl group, respectively.

5.3.7.1.3. Thiamethoxam In metabolism studies, the bulk of thiamethoxam (84–95%) was excreted in the urine with a small amount (2.5–6%) in the feces within 24 h, primarily as unchanged parent compound. This was also observed in rats, mice, ruminants, and poultry. Hydrolysis of the perhydro-1,3,5-oxadiazine ring system in thiamethoxam followed by *N*-demethylation is described as the major metabolic pathway; two other compounds are formed by loss of the *N*-nitro group from either metabolite. Reduction of the *N*-nitro group to a hydrazine, and subsequent conjugation with 2-oxo-propionic or acetic acids results in several major metabolites. Thiamethoxam metabolism was well investigated in plants like maize, rice, pears, and cucumbers. The active ingredient exhibits a systemic behavior, i.e., it is translocated via the roots into the whole plant. An accumulation was observed at the leaf borders, with very low residue levels. The same metabolites were found in cereals and fruits. An aqueous photolysis study with radiolabeled thiamethoxam indicated that the neonicotinoid degrades significantly under photolytic conditions (Schwartz *et al.*, 2000).

5.3.7.1.4. Nitenpyram The polar nitenpyram has a relatively short persistence in soil (DT_{50} 1–15 days), which probably offsets the relatively weak sorption that might otherwise lead to mobility through soils. In plants the metabolites 2-[*N*-(6-chloro-3-pyridylmethyl)-*N*-ethyl]amino-2-methyliminoacetic acid (CPMA) and *N*-(6-chloro-3-pyridylmethyl)-*N*-ethyl-*N*-methylformamidine (CPMF) were formed. Presumably CPMF was produced in the field by decarboxylation of CPMA (Tsumura *et al.*, 1998). Animal metabolism was investigated by oral administration of nitenpyram labeled with ^{14}C to rats. As a result, 95–98% of the ^{14}C administered was excerted into urine within 2 days after treatment and no accumulation of ^{14}C in the internal organs was observed. The results reflect the high water solubility (840 g l^{-1}), and the low partition coefficient ($\log P_{OW} = -0.64$ at 25 °C) of nitenpyram may contribute to its low toxicity against mammals (Akayama and Minamida, 1999).

5.3.7.1.5. Acetamiprid Acetamiprid is a mobile, rapidly biodegradable compound in most soil. The primary degradation pathway is aerobic soil metabolism. Acetamiprid is relatively stable to hydrolysis at environmental temperatures, and photodegrades relatively slowly in water, whereas it is rapidly degraded in soils to form *N*-(6-chloro-pyrid-3-yl-methyl)-*N*-methyl-amine and 6-CNA. The DT_{50} values of acetamiprid in clay loam or light clay soils were in range of 1–2 days. In soil from the field or that used in container studies, acetamiprid degraded very rapidly (half-life 12 days). The main pathway was nitrile oxidation of acetamiprid into the N-amidino derivative, which cleaved, affording the *N*-(6-chloro-pyrid-3-ylmethyl)-*N*-methyl-amine and finally to 6-CNA. Mineralization to carbon dioxide followed.

Acetamiprid accounted for the majority of the residue in the crops, and metabolites occurred in negligible amounts. The main component found in plant metabolism studies was the parent acetamiprid. Small amounts of *N*-demethylacetamiprid were formed which cleaved to give 6-CNA and to a lesser extent oxidized to 6-CPA. The latter in turn either formed a conjugate with glucose or was also thought to form a *N*-(6-chloro-pyrid-3-ylmethyl)-*N*-methylamine as a minor metabolite (Tokieda *et al.*, 1998; Roberts and Hutson, 1999) (**Figure 24**). The

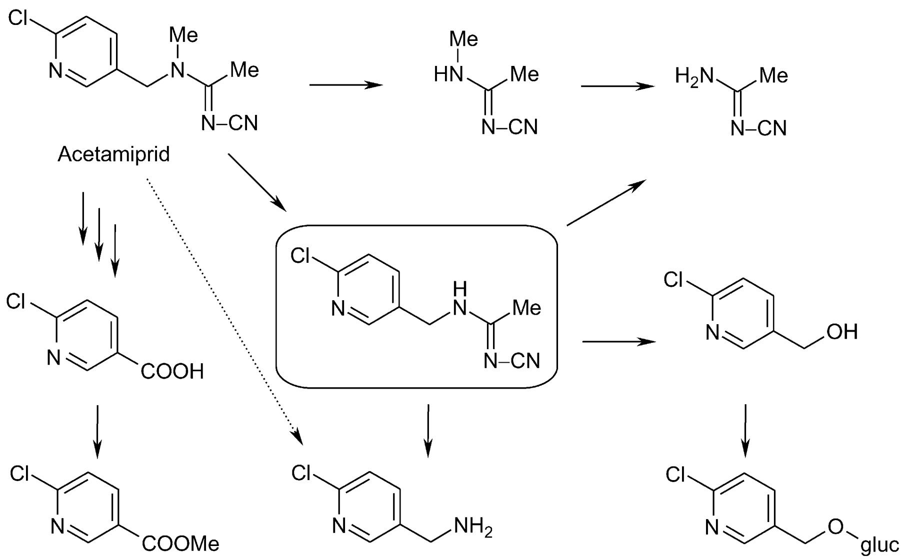

Figure 24 Proposed pathway of acetamiprid metabolism in plants. (Reproduced with permission from Roberts, T.R., Hutson, D.H. (Eds.), **1999**. Metabolic Pathways of Agrochemicals, Part 2, Insecticides and Fungicides. Cambridge University Press, Cambridge.)

metabolic fate of [2,6-^{14}C-*pyridine*]acetamiprid was investigated in eggplants and apples following application to foliage or fruit, and in cabbage plants after application to foliar and soil. Parent acetamiprid was slowly metabolized to similar products in all plants. Acetamiprid was absorbed by and penetrated the foliage well but it was poorly translocated (Roberts and Hutson, 1999).

5.3.7.1.6. Clothianidin Studies of the metabolic pathway of clothianidin in maize and sugar beet show a clear and consistent picture (Klein, 2003). The parent compound is always the major component of the residue in the edible parts of the crops. Up to seven metabolites were identified, but most of them did not exceed 10% of the total radioactive residues. Furthermore, all the main metabolites identified in plants were also detected in rat metabolism studies (Klein, 2003; Yokota *et al.*, 2003). Generally, the following reactions are involved in the metabolic pathway of clothianidin in maize and sugar beets after seed treatment application:

- *N*-demethylation to form the *N*-demethyl clothianidin and subsequent hydrolysis to produce the *N*-(2-chloro-1,3-thiazol-5-ylmethyl)urea;
- hydrolysis of the *N*′-nitroimino moiety to form *N*-(2-chloro-1,3-thiazol-5-yl)-*N*′-methylurea and subsequent *N*-demethylation to form *N*-(2-chloro-1,3-thiazol-5-yl)urea;
- denitrification (reduction) to form *N*-(2-chloro-1,3-thiazol-5-yl)-*N*-methylguanidine and C–N bond cleavage within the compound to form *N*-methylguanidine;
- C–N bond cleavage (loss of the 1,3-thiazol-5-ylmethyl moiety) to form *N*-methyl-*N*′-nitroguanidine;
- *N*-demethylation of *N*-methyl-*N*′-nitroguanidine to form *N*′-nitroguanidine;
- denitrification (reduction of *N*-methyl-*N*′-nitroguanidine to form *N*-methylguanidine);
- C–N bond cleavage of *N*-(2-chloro-1,3-thiazol-5-yl)-*N*′-nitroguanidine to form nitroguanidine; and
- C–N bond cleavage (loss of the *N*′-nitroimino moiety) and subsequent oxidation of the intermediate to form 2-chloro-1,3-thiazol-5-carboxylic acid.

Unchanged parent compound is the major constituent of the residue at harvest. The major pathway of metabolism involves *N*-demethylation of clothianidin to produce *N*-(2-chloro-1,3-thiazol-5-ylmethyl)-*N*′-nitroguanidine. In some crop parts *N*-methylguanidine made up some 20% of the residue at harvest (Klein, 2003).

5.3.8. Pharmacology and Toxicology

Because of the target site selectivity, neonicotinoids are more toxic to aphids, leafhoppers, and other sensitive insects than to mammals and aquatic life (Matsuda *et al.*, 1998; Yamamoto *et al.*, 1998; Tomizawa *et al.*, 2000; Tomizawa and Casida, 2003). Comparative binding studies on insects nAChRs indicate that their ability to displace tritiated imidacloprid from its binding site correlates well with their insecticidal efficacy (Kagabu, 1997a; Nauen *et al.*, 2001).

5.3.8.1. Safety Profile

The introduction of imidacloprid as the first CNI was a milestone in the general effort to enhance the environmental safety of crop protection agents (Krohn and Hellpointer, 2002) (**Tables 6** and 7).

5.3.8.1.1. Mammalian toxicity The safety factor of imidacloprid, that means the ratio of the lethal doses for mammals to insects, can be estimated as 7300 from the LD_{50} value of 0.062 mg kg^{-1} for *M. persicae* by topical application and an oral LD_{50} value for rats of 450 mg kg^{-1} (**Table 6**) (Elbert *et al*., 1990). Therefore imidacloprid ranks as an insecticide with high selective toxicity.

Thiacloprid possesses a low acute toxicity. Birds and mammals are at neither acute nor chronic risk when thiacloprid is applied at the recommended dose under practical conditions.

After oral dosing to rats, thiamethoxam is rapidly and completely absorbed, and up to 90% of the applied material is readily eliminated as parent compound through the urine. Thiamethoxam has a low acute toxicity when applied to rats either orally, dermally, or by inhalation (**Table 6**). The neonicotinoid is not irritant to skin and eyes, and has no sensitizing potential (Maienfisch *et al*., 1999a, 2001a). Acute and absorption subchronic neurotoxicity studies in rats showed that thiamethoxam is devoid of any neurotoxic potential. However, mechanistic studies showed thiamethoxam demonstrated a phenobarbital-like induction of enzymes in mouse liver. In repeat dose feeding studies in rodents and dogs, the liver and kidneys (rat only) were the main target organs. In life-time rodent feeding studies, mice showed an increased incidence of liver tumors, which was specific to this species since a chronic rat study showed thiamethoxam had no tumorigenic potential (Maienfisch *et al*., 2001a). A 12-month dog feeding study produced some alterations in blood chemistry, and a minimal change was seen in testes weight in two males at 1500 ppm, and tubular atrophy was observed at 750 and 1500 ppm. Dermal absorption studies in rats, and *in vitro* studies with rat and human skin, resulted in very low absorption of thiamethoxam. After an exposure time of 6 h the systemic absorption of thiamethoxam was between 0.4% and 2.7% within 6 h, and between 0.8% and 2.9% within 48 h. Oral reproductive toxicity studies showed no evidence of developmental impairment or teratogenic potential (Maienfisch *et al*., 1999a).

Nitenpyram has a minimal adverse effect against mammals (Akayama and Minamida, 1999) (**Table 6**).

Acetamiprid is of relatively low toxicity to mammals, and it has been classified as an "unlikely" human carcinogen. In mammals, acetamiprid caused generalized, nonspecific toxicity and did not appear to have specific target organ toxicity. Acetamiprid has relatively low acute and chronic toxicity in mammals, and there was no evidence of carcinogenicity, neurotoxicity, and/or endocrinic disruption. Aggregate risk estimates for acetamiprid for food and water do not raise concern for acute and chronic levels of exposure. The acute oral toxicity to male rat (LD_{50} 217 mg kg^{-1}) and mouse (LD_{50} 198 mg kg^{-1}), as well as female rat (LD_{50} 146 mg kg^{-1}) and mouse (LD_{50} 184 mg kg^{-1}) is noncritical. The acute dermal toxicity to male and female rats is low (>2000 mg kg^{-1}). Toxicological tests for acetamiprid, e.g., irritation to skin and eyes (rabbit), sensitization to skin (guinea pig), and mutagenicity, as evaluated by the Ames test, were all negative.

5.3.8.1.2. Environmental fate The fate of crop protection agents such as neonicotinoids in the environment includes its behavior in the soil, water, and air compartments (Stupp and Fahl, 2003). After application of a crop protection agent (as a formulation) to crops or in/on soil, a part of the active substance is not taken up by the plants remains, e.g., on the soil. Other parts of the agent can be transported to neighboring water bodies via drift, wind erosion, or runoff, or can enter the air by evaporation from the plant surface (Stupp and Fahl, 2003). Therefore, different physicochemical and biological processes are involved in the environmental behavior of an active substance, i.e., hydrolytic and photochemical degradation, microbial transformation and decomposition like metabolism, sorption to the soil, and translocation of the active substance and its degradation products.

Formulated imidacloprid is stable at room temperature in the dark under usual storage conditions; however, the active ingredient is labile in alkaline media (Kagabu and Medej, 1995, 2003b). Numerous field trials carried out in Europe and the USA on the degradation of imidacloprid demonstrate that the active ingredient does not accumulate in the soil (Krohn and Hellpointer, 2002). There is no likelihood of an accumulatiom occurring following repeated yearly applications. Long-term studies in the UK indicate that the maximum concentrations in the soil reaches a plateau, having a relatively low residual level ($\leq$0.030 mg kg^{-1}) (Krohn and Hellpointer, 2002). Imidacloprid is not stable in an aqueous environment, where sunlight further accelerates its degradation. Those characteristics influence the environmental behavior of imidacloprid on surface water and in water sediment such as in rivers and lakes, as well as in fog and rain. The

occurrence of imidacloprid in the air is determined by its low vapor pressure of 4×10^{-10} Pa, which excludes volatilization from treated surfaces (Krohn and Hellpointer, 2002).

Thiacloprid possesses a favorable environmental profile and will disappear from the environment after having been applied as a crop protection chemical. The effect of technical and formulated (SC 480) thiacloprid on respiratory (carbon turnover) and nitrogen mineralization rates in soil were examined in a series of 28-day studies on soil microflora (Schmuck, 2001). Thiacloprid had no adverse effect either on the microbial mineralization of nitrogen in different soil types like silty sand (0.6% org.C, pH_{KCl} 5.7) or loamy silt soil (2.3% org.C, pH_{KCl} 7.1) after addition of lucerne–grass–green meal ($5\,g\,kg^{-1}$) and at both the maximum and $10\times$ application rates (Schmuck, 2001). The half-lives in soil measured under field conditions of northern Europe ranged from 9 to 27 days, and in southern Europe from 10 to 16 days (Krohn, 2001). The major metabolites formed are only intermediates before complete mineralization to carbon dioxide occurs. Under practical field conditions thiacloprid is not toxic to earthworms (*Eisenia foetida*) or soil microorganisms (**Table 7**).

Furthermore, thiacloprid and its formulations pose a favorably low toxicity hazard to honeybees and bumblebees. Consequently, the compound can be applied to flowering crops at the recommended rates without posing a risk to bees (Calypso™ up to $200\,g\,a.i.\,ha^{-1}$). In addition, Calypso™ does not affect the pollination efficacy of pollinators (Elbert *et al.*, 2000). Thiacloprid must be classified as being only slightly mobile in soil, and hence it has low potential for leaching into groundwater. In the aquatic environment thiacloprid will also undergo rapid biotic degradation, with a half-life of 12–20 days (Krohn, 2001). Because of its low vapor pressure (3×10^{-10} Pa) and its water solubility of $0.185\,g\,l^{-1}$, the potential for its volatilization is negligible. Acute and chronic toxicity testing in fish and water-fleas (*Daphnia magna*) indicates a very low to negligible risk to these species following accidental contamination with thiacloprid by spray drift. Reproduction of water-fleas and fish was also not affected at environmentally relevant water concentrations of thiacloprid. Other aquatic invertebrates revealed a higher sensitivity to thiacloprid, especially insect larvae and amphipod species such as *Chironomus* and *Hyallela*. Insect larvae were also identified as the most sensitive species in a pond study. However, the rapid dissipation of thiacloprid in water bodies allows for a rapid recovery of affected aquatic insect populations. Algae, represented by *Scenedesmus subspicatus* and *Pseudokirchneriella subcapitata*, are not sensitive to thiacloprid. Toxicity exposure ratio values indicate a high margin of safety for algal species. Harmful concentrations of thiacloprid or its metabolites are most unlikely in aquatic ecosystems. There is no potential for bioconcentration in fish due to the log P_{OW} of 1.26 for thiacloprid. The metabolites occurring in groundwater are of no concern as noted by toxicological, ecotoxicological, and biological testing.

In laboratory soils, thiamethoxam degrades at moderately slow rates (Maienfisch *et al.*, 1999a). The compound is photolyzed rapidly in water. In natural aquatic systems, e.g., rice paddies, degradation also occurs in the absence of light by microbial degradation. Based on the low vapor pressure (**Table 3**) and the results of soil volatility studies, significant volatilization is not expected. Thiamethoxam has a low toxicity by ingestion to birds, and is practically nontoxic to fish, *Daphnia* and molluscs. In addition, the earthworm species *E. foetida* and green algae were also found to be insensitive (Maienfisch *et al.*, 2001a). Thiamethoxam can be classified as slightly to moderately harmful to most beneficial insects, but safe to predatory mites in the field (Maienfisch *et al.*, 1999a). Alternatively, thiamethoxam and all other nitroguanidines have to be considered toxic to bees. However, thiamethoxam showed no bioaccumulation potential, and is moderately mobile in soil and degrades at fast to moderate rates under field conditions (Maienfisch *et al.*, 1999a).

Nitenpyram rapidly decomposed in water, under the conditions of 12 000 lux irradiation intensity using a 500 W xenon lamp (half-life at pH 5, 18–21 min; in purified water, 16 min), and in soil under aerobic conditions (half-lives flooded <1 day; upland 1–3 days) (Akayama and Minamida, 1999).

Toxicity of acetamiprid to fish and *Daphnia* is very low, with LD_{50} values for carp and *Daphnia* of $>100\,mg\,l^{-1}$ and $>1000\,mg\,l^{-1}$, respectively (Yamada *et al.*, 1999). Acetamiprid shows less adverse effects on both natural and enemies, such as predaceous mites, and beneficial insects, as well as honeybee and bumblebee (Takahashi *et al.*, 1998).

Chlothianidin degraded moderately under field conditions and was found to be a neonicotinoid of medium mobility based on laboratory experiments (Stupp and Fahl, 2003). With regard to its behavior in aquatic environments, photolysis contributes significantly to degradation, and clothianidin finally mineralizes to carbondioxide. Its degradation in water/sediment systems under aerobic conditions is moderate. The main part of the applied active

substance is bound irreversibly to the sediment, thus avoiding subsequent contamination (Stupp and Fahl, 2003). In addition, in a water/sediment study degradation of clothianidin was observed to be significantly faster (factor 2–3) under anaerobic conditions than in aerobic conditions (Stupp and Fahl, 2003). Based on the physicochemical properties of clothianidin (see Section 5.3.3.4) no volatilization, and thus, no significant amounts of this compound can be expected in the atmosphere. Therefore clothianidin does not appear to represent a risk for the environment.

5.3.9. Resistance

Resistance in arthropod pest species comprises a change in the genetic composition of a population in response to selection by pesticides, such that control of the pest species in the field may be impaired at the recommended application rates. Selection for resistance in pest populations (including weeds, fungi, mites, and insects) due to frequent applications of agrochemicals has been one of the major problems in modern agriculture. Resistance to insecticides and acaricides appeared very early, and the extent and economic impact remain greater than for other agrochemicals. Between the beginning of the last century and the mid-1950s, the number of resistant arthropod species grew gradually with only a few resistant species described per decade. However, this rate increased markedly after the introduction of the organophosphates to more than 30 new resistant species every 2 years through the early 1980s. Ten years later, more than 500 arthropod species were known to be resistant to at least one insecticide or acaricide (Georghiou, 1983; Green *et al*., 1990). Among them are 46 hopper and aphid species, which show in some cases very high levels of resistance to conventional types of insecticide chemistry, i.e., organophosphates, and carbamate and pyrethroid insecticides. The invention and subsequent commercial development of neonicotinoid insecticides, such as imidacloprid, has provided agricultural producers with invaluable new tools for managing some of the world's most destructive crop pests, primarily those of the order Hemiptera (aphids, whiteflies, and planthoppers) and Coleoptera (beetles), including species with a long history of resistance to earlier-used products (**Figure 20**). However, the speed and scale with which imidacloprid, the commercial forerunner of neonicotinoids, was incorporated into control strategies around the world prompted widespread concern over the development of imidacloprid resistance (Cahill *et al*., 1996; Denholm *et al*., 2002).

To a large extent these pessimistic forecasts have not been borne out in practice. Imidacloprid has proved remarkably resilient to resistance, and cases of resistance that have been reported are still relatively manageable and/or geographically localized. The existence of strong resistance in some species has nonetheless demonstrated the potential of pests to adapt and resist field applications of neonicotinoids. The ongoing introduction of new molecules (e.g., acetamiprid, thiamethoxam, nitenpyram, thiacloprid, and clothianidin), unless carefully regulated and coordinated, seems bound to increase exposure to neonicotinoids, and to enhance conditions favoring resistant phenotypes.

5.3.9.1. Activity on Resistant Insect Species

The incidence and management of insect resistance to neonicotinoid insecticides was recently reviewed by Denholm *et al.* (2002). Resistance to neonicotinoid insecticides is still rare under field conditions and baseline susceptibility data have been provided in the past and more recently especially for imidacloprid in order to monitor for early signs of resistance in some of the most destructive pest insects (Cahill *et al*., 1996; Elbert *et al*., 1996; Elbert and Nauen, 1996; Foster *et al*., 2003; Nauen and Elbert, 2003; Rauch and Nauen, 2003; Weichel and Nauen, 2003). Baseline susceptibility data and derived diagnostic concentrations to monitor resistance are usually calculated from composite log-dose probit-mortality lines, including the combined curves of several strains of a certain pest collected from all over the world or at least different parts of the world where the compound is supposed to be used. A compilation for imidacloprid of such data is given for some of the most important pests, i.e., *Myzus persicae, Aphis gossypii, Phorodon humuli, Bemisia tabaci, Trialeurodes vaporariorum*, and *Leptinotarsa decemlineata* (**Table 8**).

There have been only low levels of tolerance detected in European and Japanese samples of *M. persicae* (Devine *et al*., 1996; Nauen *et al*., 1996), but it was not possible to link this tolerance to specific biochemical markers (Nauen *et al*., 1998a). In most cases the lower susceptibility to imidacloprid and other neonicotinoids was correlated with a decreased efficacy of nicotine (Devine *et al*., 1996; Nauen *et al*., 1996). Furthermore differences in hardiness were sometimes observed in field strains bioassayed directly upon receipt, which allow strains to survive longer in comparison to susceptible laboratory populations, when exposed to imidacloprid-treated leaves (Nauen and Elbert, 1997). However, such effects disappeared when the exposure time (especially in systemic bioassays) was extended

Table 8 Baseline susceptibility of some high risk pests to imidacloprid

Species	*Diagnostic dose*	*Bioassay system/assessment time*	*Reference*
Myzus persicae	15 ppm	Leaf dip (6-well plate)	Nauen and Elbert (2003)
Myzus persicae	2.25 ng per aphid	Topical	Foster *et al.* (2003)
Aphis gossypii	13 ppm	Leaf dip (6-well plate)	Nauen and Elbert (2003)
Phorodon humuli	13 ppm	Leaf dip (6-well plate)	Weichel and Nauen (2003)
Bemisia tabaci	16 ppm	Systemic bioassay	Cahill *et al.* (1996)
Bemisia tabaci	1 ppm	Leaf dip	Rauch and Nauen (2003)
Leptinotarsa decemlineata	8 ppm	Artificial diet (larvae)	Olson *et al.* (2000)
Leptinotarsa decemlineata	0.2 μg per beetle	Topical (adult)	Nauen (unpublished data)

from 48 h to 72 h, and also after maintaining such strains under laboratory conditions for some weeks (Nauen and Elbert, 1997). More recently Foster *et al.* (2003b) demonstrated that tolerance to imidacloprid in *M. persicae* from different regions in Europe also provided cross-tolerance to acetamiprid. The authors were able to show a clear correlation between ED_{50} values of acetamiprid and imidacloprid for strains with a different degree of tolerance. However, tolerance factors compared to a susceptible reference population never exceeded factors of 20, and field failures were not seen (Foster *et al.*, 2003b).

One species of major concern over the last decade is the tobacco or cotton whitefly, *B. tabaci*; this is a serious pest in many cropping systems worldwide and several biotypes of this species have been described (Perring, 2001). The most widespread biotype is the B-type, which is also known as *B. argentifolii* Bellows & Perring. The B-type whitefly is a common pest, particularly in cotton, vegetables, and ornamental crops, both by direct feeding and as a vector of numerous plant pathogenic viruses. In southern Europe, it coexists with another biotype, the Q-type, which was originally thought to be restricted to the Iberian peninsula, but which is now also known to occur in some other countries throughout the Mediterranean area, including Italy and Israel (Brown *et al.*, 2000; Palumbo *et al.*, 2001; Nauen *et al.*, 2002; Horowitz *et al.*, 2003). The biotypes B and Q can easily be distinguished by randomly amplified polymorphic DNA polymerase chain reaction (RAPD-PCR) or native polyacrylamide gel electrophoresis (PAGE) and subsequent visualization of their nonspecific esterase banding pattern (Guirao *et al.*, 1997; Nauen and Elbert, 2000).

As a consequence of extensive exposure to insecticides, *B. tabaci* has developed resistance to a wide range of chemical control agents (Cahill *et al.*, 1996). The need for a greater diversity of chemicals for whitefly control in resistance management programs has been met by the introduction of several insecticides with new modes of action, which are unaffected by mechanisms of resistance to organophosphates or pyrethroids. Since the introduction of imidacloprid, the neonicotinoids have been the fastest-growing class of insecticides. Imidacloprid exhibits an excellent contact and systemic activity and therefore has been largely responsible for the sustained management of *B. tabaci* in horticultural and agronomic production systems worldwide. Beside imidacloprid, there are other neonicotinoids with good efficacy against whiteflies, e.g., acetamiprid and thiamethoxam.

In Israel, monitoring of resistance in *B. tabaci* to imidacloprid and acetamiprid was initiated in 1996 in cotton and greenhouse ornamental crops. After 2 years of use in cotton, no apparent resistance to imidacloprid and acetamiprid was reported (Horowitz *et al.*, 1998). However, 3 years of acetamiprid use in greenhouses in Israel resulted in a 5–10-fold decrease in susceptibility of *B. tabaci* to acetamiprid (Horowitz *et al.*, 1999). In the past only a few cases of lowered neonicotinoid susceptibility in B-type *B. tabaci* have been described, among them strains from Egypt and Guatemala that were recently reported (El Kady and Devine, 2003; Byrne *et al.*, 2003). In Arizona, where imidacloprid has been used since 1993, monitoring of *B. tabaci* populations from cotton fields, melon fields, and greenhouse vegetables suggested reduced susceptibility to imidacloprid from 1995 to 1998, but subsequent monitoring showed that these populations had actually regained and sustained susceptibility to imidacloprid in 1999 and 2000 (Li *et al.*, 2000, 2001). Furthermore, imidacloprid use in Arizona and California remains high, but no signs of reduced control in the field have been reported yet (Palumbo *et al.*, 2001). B-type whiteflies have been shown to develop resistance to imidacloprid under selection pressure in the laboratory (Prabhaker *et al.*, 1997). There was a moderate increase of resistance of up to 17-fold in the first 15 generations, but 82-fold resistance after 27 generations. However, resistance was not stable and disappeared after a few generations without insecticide pressure. Resistance to

imidacloprid conferring a high level of cross-resistance to thiamethoxam and acetamiprid was first demonstrated, and best studied in Q-type *B. tabaci* from greenhouses in the Almeria region of southern Spain, but was also detected in single populations from Italy and recently Germany as well (Nauen and Elbert, 2000; Nauen *et al.*, 2002; Rauch and Nauen, 2003). Neonicotinoid resistance seem to remain stable in all field-collected Q-type strains maintained in the laboratory without further selection pressure (Nauen *et al.*, 2002). Neonicotinoid cross-resistance was also reported in B-type whiteflies from cotton in Arizona but at lower levels (Li *et al.*, 2000). More recently a high level of cross-resistance between neonicotinoids was also described in a B-type strain of *B. tabaci* from Israel, and resistance factors detected in a leaf-dip bioassay exceeded 1000-fold (Rauch and Nauen, 2003).

The Colorado potato beetle, *L. decemlineata* has a history of developing resistance to virtually all insecticides used for its control. The first neonicotinoid, i.e., imidacloprid was introduced for controlling Colorado potato beetles in North America in 1995. Concerns over resistance development were reinforced when extensive monitoring of populations from North America showed about a 30-fold variation in LC_{50} values from ingestion and contact bioassays against neonates (Olsen *et al.*, 2000). Much of this variation appeared unconnected with imidacloprid use, and was probably a consequence of cross-resistance from chemicals used earlier. Lowest levels of susceptibility occurred in populations from Long Island, New York, an area that has experienced the most severe resistance problems of all with *L. decemlineata*. Zhao *et al.* (2000) and Hollingworth *et al.* (2002) independently studied single strains collected from different areas in Long Island, both treated intensively with imidacloprid between 1995 and 1997. In the first study, grower's observations of reduced control were supported by resistance ratios for imidacloprid of 100-fold and 13-fold in adults and larvae, respectively. The second study reported 150-fold resistance from topical application bioassays against adults. In this case the strain was also tested with thiamethoxam, which had not been used for beetle control at the time of collection. Interestingly, resistance to thiamethoxam (about threefold) was far lower than to imidacloprid.

Other reports referring to resistance to neonicotinoid insecticides were on species of lesser importance, including species either from field-collected populations or artificially selected strains. Among these were the small brown planthopper, *Laodelphax striatellus* (Sone *et al.*, 1997), western flower thrips, *Franklienella occidentalis* (Zhao *et al.*, 1995), houseflies, *Musca domestica* and German cockroach, *Blattella germanica* (Wen and Scott, 1997), *Drosophila melanogaster* (Daborn *et al.*, 2001), *Lygus hesperus* (Dennehy and Russell, 1996), and brown planthoppers, *Nilaparvata lugens* (Zewen *et al.*, 2003).

5.3.9.2. Mechanisms of Resistance

Many pest insects and spider mites have developed resistance to a broad variety of chemical classes of insecticides and acaricides, respectively (Knowles, 1997; Soderlund, 1997). One of the three major classes of mechanisms of resistance to insecticides in insects is allelic variation in the expression of target proteins with modified insecticide binding sites, e.g., acetylcholinesterase insensitivity towards organophosphates and carbamates, voltage-gated sodium channel mutations responsible for knockdown resistance to pyrethroids, and a serine to alanine point mutation (*rdl* gene) in the γ-aminobutyric acid (GABA)-gated chloride channel ($GABA_A$-R) at the endosulfan/fipronil/dieldrin binding site (ffrench-Constant *et al.*, 1993; Williamson *et al.*, 1993, 1996; Mutero *et al.*, 1994; Feyereisen, 1995; Dong, 1997; Soderlund, 1997; Zhu and Clark, 1997; Bloomquist, 2001; Gunning and Moores, 2001; Siegfried and Scharf, 2001). The second – and often most important – class of resistance mechanisms in insect pest species is metabolic degradation involving detoxification enzymes such as microsomal cytochrome P-450 dependent monooxygenases, esterases, and glutathione *S*-transferases (Hodgson, 1983; Armstrong, 1991; Hemingway and Karunarantne, 1998; Bergé *et al.*, 1999; Devonshire *et al.*, 1999; Feyereisen, 1999; Hemingway, 2000; Field *et al.*, 2001; Scott, 2001; Siegfried and Scharf, 2001). The third, least important mechanism is an altered composition of cuticular waxes which affects penetration of toxicants. Reduced penetration of insecticides through the insect cuticle has often been described as a contributing factor, in combination with target site insensitivity or metabolic detoxification (or both), rather than functioning as a major mechanism on its own (Oppenoorth, 1985). Most of the mechanisms mentioned above affect in many cases the efficacy of more than one class of insecticides, i.e., constant selection pressure to one chemical class could to a greater or lesser extent confer cross-resistance to compounds from other chemical classes (Oppenoorth, 1985; Soderlund, 1997).

When the first neonicotinoid insecticide was introduced to the market in 1991, aphids were considered to be high risk pests with regard to their potential to develop resistance to this class of

chemicals. They have a high reproductive potential, and extremely short life cycle allowing for numerous generations in a growing season. Combined with frequent applications of insecticides that are usually required to maintain aphid populations below economic thresholds, resistance development is facilitated in these species, resulting in control failures. Such control failures have been reported for organophosphorus compounds for many decades, and more recently also for pyrethroids (Foster *et al*., 1998, 2000; Devonshire *et al*., 1999; Foster and Devonshire, 1999).

One of the major aphid pests is the green peach aphid, *M. persicae*. Resistance of *M. persicae* to insecticides is conferred by increased production of a carboxylesterase, named E4 or FE4, which provides cross-resistance to carbamates, organophosphorus, and pyrethroid insecticides (Devonshire and Moores, 1982; Devonshire, 1989). This esterase overproduction was shown to be due to gene amplification (Field *et al*., 1988, 2001). It was the sole resistance mechanism reported in *M. persicae* for more than 20 years, and only recently an insensitive (modified) acetylcholinesterase was described as a contributing factor in carbamate resistance in *M. persicae* (Moores *et al*., 1994a, 1994b; Nauen *et al*., 1996). The insensitive acetylcholinesterase in *M. persicae* confers strong resistance to pirimicarb, and a little less to triazamate (Moores *et al*., 1994a, 1994b; Buchholz and Nauen, 2001). Due to the improvement of molecular biological techniques, Martinez-Torres *et al.* (1998) recently showed that knockdown resistance to pyrethroids, caused by a point mutation in the voltage-gated sodium channel, is also present in *M. persicae*. In summary, resistance to all major classes of aphicides occurs in *M. persicae*; however, the only class of insecticides not yet affected by any of the mechanisms described above are the neonicotinoids, including its most prominent member imidacloprid (Elbert *et al*., 1996, 1998a; Nauen *et al*., 1998a; Horowitz and Denholm, 2001).

The most comprehensive studies on the biochemical mechanisms of resistance to neonicotinoid insecticides using an agriculturally relevant pest species were performed in whiteflies, *B. tabaci* (Nauen and Elbert, 2000; Nauen *et al*., 2002; Rauch and Nauen, 2003; Byrne *et al*., 2003). Biochemical examinations revealed that neonicotinoid resistance in Q-type *B. tabaci* collected in 1999 was not associated with a lower affinity of imidacloprid to nAChRs in whitefly membrane preparations (Nauen *et al*., 2002). This was confirmed more recently by testing strains ESP-00, GER-01, and ISR-02 obtained in the years 2000–2002 by Rauch and Nauen (2003). Although neonicotinoid resistance was very high in these strains (up to 1000-fold), the authors found just a 1.3-fold and 1.7-fold difference in binding affinity between strains, and concluded that target site resistance is not involved in neonicotinoid resistance in those strains investigated. Piperonyl butoxide, a monooxygenase inhibitor, is generally used as a synergist to suppress insecticide resistance conferred by microsomal monooxygenases. Experiments with whiteflies pre-exposed to piperonyl butoxide suggested a possible involvement of cytochrome P-450 dependent monooxygenases in neonicotinoid resistance (Nauen *et al*., 2002). Rauch and Nauen (2003) biochemically confirmed that whiteflies resistant to neonicotinoid insecticides showed a high microsomal 7-ethoxycoumarin O-deethylase activity, i.e., up to eightfold higher compared with neonicotinoid susceptible strains. Furthermore, this enhanced monooxygenase activity could be correlated with imidacloprid, thiamethoxam, and acetamiprid resistance. Significant differences between glutathione *S*-transferase and esterase levels were not found between neonicotinoid resistant and susceptible strains of *B. tabaci* (Rauch and Nauen, 2003). Several metabolic investigations in plants and vertebrates showed that imidacloprid and other neonicotinoids undergo oxidative degradation, which may lead to insecticidally toxic and nontoxic metabolites (Araki *et al*., 1994, Nauen *et al*., 1999b; Schulz-Jander and Casida, 2002). Metabolic studies in *B. tabaci in vivo* revealed that the main metabolite in neonicotinoid-resistant strains is 5-hydroxy-imidacloprid, whereas no metabolism could be detected in the susceptible strain (**Figure 23**) (see Section 5.3.7.1.1). One can therefore suggest that oxidative degradation is the main route of imidacloprid detoxification in neonicotinoid resistant Q-type whiteflies (Rauch and Nauen, 2003). Compared to imidacloprid, the 5-hydroxy metabolite showed a 13-fold lower binding affinity to whitefly nAChR. This result was in accordance with previous studies with head membrane preparations from the housefly (Nauen *et al*., 1998). The binding affinity expressed as the IC_{50} was highest with olefine (0.25 nM) > imidacloprid (0.79) > 5-hydroxy (5 nM) > 4-hydroxy (25 nM) > dihydroxy (630 nM) > guanidine and urea (>5000 nM). The biological efficacy in feeding bioassays with aphids correlated also with the relative affinities of the metabolites towards the housefly nAChR (Nauen *et al*., 1998b). The lower binding affinity of 5-hydroxy-imidacloprid compared to imidacloprid coincides with its lower efficacy against *B. tabaci* in the sachet test (17-fold). These data show that differences between binding to the

nAChR are comparable to the efficacy differences in adult bioassays (Rauch and Nauen, 2003).

Daborn *et al*. (2001) described *D. melanogaster* mutants exhibiting an eight- and sevenfold resistance to imidacloprid and DDT, respectively, which showed an overexpression of the P-450 gene *Cyp6g1*. However, it was not tested whether recombinant Cyp6g1 itself can metabolize imidacloprid; potentially it could metabolize a *trans*-acting factor which then upregulates presently uncharacterized P-450 genes. However, it was demonstrated that the recombinant cytochrome P-450 isozyme CYP3A4 from human liver can selectively metabolize the imidazolidine moiety of imidacloprid, resulting in 5-hydroxy-imidacloprid as the major metabolite (Schulz-Jander and Casida, 2002). It would therefore be fruitful to investigate if homologs of *Cyp6g1* and *Cyp3a4*, or similar genes, are present in the *B. tabaci* genome, and if overexpression of these genes is associated with neonicotinoid resistance.

Although considerable resistance to neonicotinoid insecticides was also reported for populations of the Colorado potato beetle from Long Island, NY, the underlying mechanisms associated have not been very well studied. Pharmacokinetic investigations on susceptible and resistant strains did not reveal any differences in the uptake and excretion of ^{14}C-labeled imidacloprid, nor were there any differences in metabolic conversion found (Hollingworth *et al*., 2002). The authors suggested a modification of the target site to be responsible for the observed resistance. But, preliminary investigations revealed no differences between resistant and susceptible strains in receptor binding studies using [^{3}H]imidacloprid (Nauen and Hollingworth, unpublished data).

Resistance development to imidacloprid would be disastrous in many regions, so there is a demand for an effective resistance management program, and interest in finding and developing new active ingredients for pest control.

5.3.9.3. Resistance Management

Monitoring and detection of insecticide resistance in order to recommend and implement effective resistance management strategies is currently one of the most important areas of applied entomology. This program is necessary to sustain the activity of as many active ingredients with different modes of action as possible by using alternate spray regimes, rotation, and sophisticated application techniques (Denholm and Rowland, 1992; McKenzie, 1996; Denholm *et al*., 1998, 1999; Horowitz and Denholm, 2001). Historically, the problem of insecticide resistance was tackled by continuously introducing new active ingredients for pest insect control. The number of insecticides available is high, but the biochemical mechanisms targeted by all these compounds is rather limited (Casida and Quistad, 1998; Nauen and Bretschneider, 2002). A pronounced decline in the introduction of new insecticides since the late 1970s revealed the limitations of a strategy relying on the continuous introduction of new active compounds (Soderlund, 1997).

This problem has been recognized by the regulatory authorities; and the European Plant Protection Organization (EPPO) recently published guidelines outlining the background work on resistance required for registration of a new active ingredient (Heimbach *et al*., 2000). These requirements, which are provided by agrochemical companies as an essential part of the registration dossier, include

- baseline susceptibility studies (testing several strains of a target species known to be prone to resistance development);
- monitoring (continuous studies on the development of resistance of target species by simple bioassays after the launch of a new compound); and
- possible resistance management strategies (how the new compound should be combined with others in order to expand its life time in the field).

5.3.10. Applications in Nonagricultural Fields

Because of the high insecticidal efficacy together with its nonvolatility and stability under storage conditions, imidacloprid (Premise®) has been successfully applied as a termiticide (Jacobs *et al*., 1997a; Dryden *et al*., 1999), and has also been used for control of turf pests such as white grubs (Elbert *et al*., 1991). Furthermore, imidacloprid is the active ingredient of the insecticide Merit®, and is commonly incorporated into fertilizers for early control of grubs in turf (Armbrust and Peeler, 2002). In addition, imidacloprid was the first neonicotinoid to be used in a gel bait formulation for cockroach control. The imidacloprid gel showed outstanding activity even after 27 months' under various conditions (Pospischil *et al*., 1999). As an endoparasiticide imidacloprid exerted activity against the gastrointestinal nematode *Haemonchus contortus* in sheep only at higher concentrations (Mencke and Jeschke, 2002). Synergistic mixtures containing imidacloprid are patented and these are useful against textile-damaging insects, such as

moth (*Tineola bisselliella, Tinea pellionella*) and beetles (*Attagenus, Anthrenus*) (Mencke and Jeschke, 2002). Salmon-parasitizing crabs are controlled by addition of 100 ppm imidacloprid to seawater (Mencke and Jeschke, 2002). Due to its toxicological properties – favorable mammalian safety characteristics (Yamamoto *et al*., 1995) (**Table 6**), the absence of eye/skin irritation and skin sensitization potential – imidacloprid has been developed for control of lice in humans (Mencke and Jeschke, 2002) and veterinary medicine (Werner *et al*., 1995). Imidacloprid (worldwide trademark: Advantage®) is the first neonicotinoid to have been developed for topical application in animals (Griffin *et al*., 1997) (see Section 5.3.10.1).

Nitenpyram (Capstar®), a fast-acting, orally administered flea treatment, is absorbed into blood of the host animal, and is thus readily available for uptake by feeding fleas (Rust *et al*., 2003). Therefore, administration of nitenpyram is effective in eliminating adult fleas for up to 48 h after treatment.

5.3.10.1. Imidacloprid as a Veterinary Medicinal Product

The cat flea (*Ctenocephalides felis*), the primary ectoparasite of companion animals worldwide, will feed on a wide variety of animals in addition to cats and dogs (Rust and Dryden, 1997), although it is not equally well adapted to all hosts (Williams, 1993). Fleas threaten the health of humans and animals due to bite reactions and transmission of diseases (Krämer and Mencke, 2001), and in addition are major nuisance pests. Therefore, flea control, is necessary.

In veterinary medicine, fleas are the primary cause for flea allergic dermatitis. This dermatitis results when the adult flea injects saliva into the host during blood feeding, which accelerates immunological response, leading to secondary infections of the skin.

The last aspect of veterinary importance is the role of fleas in disease, for example, transmission of the cestode *Dipylidium caninum*. The role of fleas in human disease transmission has been known since historic times. The Oriental rat flea (*Xenopsylla cheopis*) is the major transmitter of *Yersinia pestis*, the bacterium that causes the bubonic plague in humans. The cat flea is also capable of transmitting *Y. pestis*, and human plague cases and even deaths associated with infected cats and dogs have been occasionally reported (Rust *et al*., 1971).

Furthermore, a variety of bacteria and viruses have been reported to be transmitted by the dog flea (*C. canis*) as well as the cat flea (*C. felis*) (Krämer and Mencke, 2001). Moreover, cat owners have a high incidence of cat scratch fever, a zoonotic disease caused by the Gram-negative bacterium *Bartonella henselae*. Recent research showed that flea feces are the major means of disease transmission between cats, and from cats to humans (Malgorzata *et al*., 2000).

5.3.10.1.1. Insecticidal efficacy in veterinary medicine Recommendations for the treatment of fleas on companion animals, and the selection of an insecticide and its formulation, are generally based upon the species and age of the animal to be treated, the level of infestation, the rate of potential reinfestation, and the thoroughness of environmental treatment. However, the selection of an insecticide formulation by a pet owner is actually based on economics and the product's ease of use (Williams, 1993). Another factor in the choice of a flea treatment by pet owners is the safety and toxicology of the insecticide (Krämer and Mencke, 2001).

Imidacloprid, 10% spot-on, was designed to offer a dermal treatment, which means it is applied externally onto a small dorsal area (a spot) of the animal's skin. Criteria for the selection of an appropriate topical flea formulation are good solubility of the compound, good adhesion to the skin, good spreading properties, good local and systemic tolerance, stability, and compatibility with legal standards. The imidacloprid spot-on formulation, which meets all these requirements, contains 10 g a.i. in 100 ml nonaqueous solution. The efficacy of this formulation for flea control on cats and dogs has been reported (Krämer and Mencke, 2001). Imidacloprid applied at the target therapeutic dosage of 10.0 $mg\,kg^{-1}$ killed 99% of the fleas within 1 day of treatment, and continued to provide 99–100% control of further flea infestation for at least 4 weeks (Hopkins *et al*., 1996; Arther *et al*., 1997) (**Figure 25**).

Studies using flea-infested cats (Jacobs *et al*., 1997b) proved that imidacloprid possess considerable potency against adult fleas on cats, and retains a high level of activity for 4–5 weeks. Imidacloprid was effective for both immediate relief from an existing flea burden (the therapeutic effect), and for longer-term flea control (the prevention or prophylactic effect) (**Table 9**). Imidacloprid spreads and acts using animal skin as the main carrier. The compound was shown to be localized in the water-resistant lipid layer of the skin surface, produced by sebaceous glands, and spread over the body surface and onto the hair (Mehlhorn *et al*., 1999). Insecticide spread over the skin surface was also reported from a clinical study that observed fast onset of flea control, as early as 6 h posttreatment (Everett *et al*., 2000). Therefore if the superficial fatty layer of

the skin is removed by repeated swabbing with alcohol fleas consumed the same amount of blood in treated and untreated dogs. Thus imidacloprid localized in the lipid layer of the skin acts on adult fleas by contact. It was reported that imidacloprid is not taken up by the flea during blood feeding, but is absorbed via the flea's smooth, nonsclerotized intersegmental membranes that are responsible for the insect's mobility. Mehlhorn *et al.* (1999) concluded that this seems reasonable because of imidacloprid's lipophilicity renders it incapable of passing through the sclerotized cuticle. Moreover, initial damage was seen in the ganglia close to the ventral body side (i.e., in subesophageal and thoracic ganglia). Fleas affected by imidacloprid treatment showed characteristic pathohistological changes (Mehlhorn *et al.*, 1999). Muscle fibers and tissue around the subesophageal ganglion were damaged, with the mitochondria and axons showing intensive vacuolization (**Figure 26**). Imidacloprid's mode of action corresponded with the structural findings (Mehlhorn *et al.*, 1999), which showed overall destruction of the mitochondria, damage of the nerve cells, and disintegration of the insect muscles (**Figure 26**).

Imidacloprid's activity on ectoparasitic insects results from its presence within the lipid layer of the host body surface. Since this lipid layer is always present, imidacloprid remains available for a prolonged time (Hopkins *et al.*, 1996; Mehlhorn *et al.*, 2001a), and reduces the likelihood of its removal during water exposure (Mehlhorn *et al.*, 1999).

The spectrum of imidacloprid activity to ectoparasites is not confined to fleas. It has also proven to be highly effective against both sucking lice (*Linognathus setosus*), and biting or chewing lice (*Trichodectes canis*) (Hanssen *et al.*, 1999). Furthermore imidacloprid acted rapidly on all motile stages of sheep keds (Mehlhorn *et al.*, 2001b). Sheep keds of the species *Melophagus ovinus* are wingless parasitic insects belonging to the dipteran family Hippobiscidae. Besides skin infection, which results in the loss wool quality and meat production, sheep keds are also known to transmit diseases, such as trypanosomiasis. However, ticks did not prove to

Res. 85*, 625–637.)

be sensitive to complete control by imidacloprid (Young and Ryan, 1999).

5.3.10.1.2. Larvicidal activity Apart from the fast-acting adulticidal activity of imidacloprid on flea populations, its larvicidal effects have also been investigated. Reinfestation of animals, from earlier deposited eggs, larvae, and preemerged adult fleas, can be overcome by the use of effective larvicidal compounds or insecticides acting on both the adult and the immature stages of fleas. In early studies using imidacloprid, larvicidal activity was observed in the immediate surrounding of treated dogs (Hopkins *et al.*, 1997). Skin debris collected from treated dogs, when mixed into flea rearing media, showed high flea larva mortality. In repeated tests using the skin debris samples, collected at day 7 post-treatment, the larval mortality remained high at

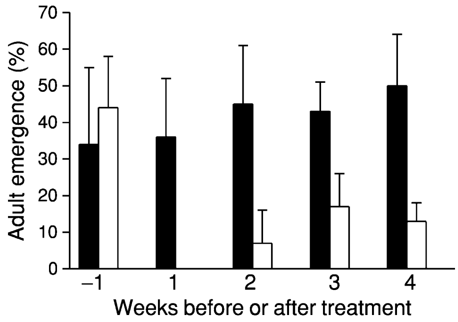

Figure 27 Emergence of adult fleas from flea eggs incubated on blankets used by untreated (control) or imidacloprid treated cats. (Reproduced from Jacobs, D.E., Hutchinson, M.J., Ewald-Hamm, D., **2000**. Inhibition of immature *Ctenocephalides felis felis* (Siphonaptera: Pulicidae) development in the immediate environment of cats treated with imidacloprid. *J. Med. Entomol. 37*, 228–230.)

100% even after 51 days (Arther *et al.*, 1997). In *in vitro* studies, flea larvae survived for only 6 h when placed on clipped hair from imidacloprid treated dogs (Mehlhorn *et al.*, 1999). Similar results have also been reported for cats (Jacobs *et al.*, 2000). Adult flea emergence was reduced by 100%, 84%, 60%, and 74% in the first, second, third, and fourth week postimidacloprid treatment, in comparison to untreated controls (Figure 27). This persistent larvicidal activity is important, because in the absence of any larvicidal effect of an applied adulticide, reinfestation would occur from eggs deposited prior to treatment (Jacobs *et al.*, 2001). Furthermore, cats wander freely outdoors, and thus may visit sites shared with other flea-infested domestic or wild animals.

5.3.10.1.3. Flea allergy dermatitis (FAD) FAD is a disease in which a hypersensitive state is produced in a host in response to the injection of antigenic material from flea salivary glands (Carlotti and Jacobs, 2000). Synonyms for FAD include flea bite allergy and flea bite hypersensitivity. In cats, the disease is also known as feline miliary dermatitis and feline eczema. FAD is one of the most frequent causes of skin conditions in small animals, and a major clinical entity in dogs. FAD is the commonest nonroutine reason for pet owners to seek veterinary advice. Hypersensitivity to flea bites is not only of importance to domestic pets, but is also an important cause of the common skin disease in humans, termed papular urticaria. Detailed investigations carried out on patients exposed to flea-infested pets have shown that the incidence of such reactions is quite high.

Several field studies have been conducted, focusing on the efficacy of imidacloprid on cats and dogs with clinical signs of FAD (Krämer and Mencke, 2001). The efficacy of imidacloprid in flea removal,

and the resolution of FAD was tested in dogs and cats from single- and multiple-animal households (Genchi *et al.*, 2000). Flea infestation was examined and FAD dermatitis lesions were ranked according to severity of typical clinical signs. Flea numbers dropped significantly after treatment of animals from both single- and multiple-animal households. In dogs clinical signs of FAD prior to treatment, decreased from 38% to 16% by day 14, and 6% by day 28, thus verifying a rapid adulticidal and high residual activity that lasted at least 4 weeks. There was an effective control of parasites, with rapid improvement of allergy until almost complete remission up to 28 days following the first application. Recently studies on the effect of imidacloprid on cats with clinical signs of FAD confirmed field data published by Genchi *et al.* (2000). Clinical signs of FAD, especially alopecia and pruritus were resolved after monthly treatment using imidacloprid (Keil *et al.*, 2002) (**Figure 28**). Furthermore, controlling FAD is enhanced when blood feeding of fleas is reduced. This so-called "sublethal effect" or "antifeeding effect" was reported using very low concentrations of imidacloprid (Rust *et al.*, 2001, 2002).

5.3.10.1.4. Imidacloprid as combination partner in veterinary medicinal products The ability of acaricides to repel or kill ticks, before they attach to a host and feed, is important for the prevention of transmission of tick born pathogens (Young *et al.*, 2003). K9 Advantix™, an effective tick control agent (Spencer *et al.*, 2003, Mehlhorn *et al.*, 2003), is a spot-on product containing 8.8% (w/w) imidacloprid and 44% (w/w) permethrin. The mixture repels and kills four species of ticks, including *Ixodes scapularis*, for up to 4 weeks. It also repels and kills mosquitoes, and kills flea adults and larvae. Furthermore, a combination containing imidacloprid 10% (w/v) and permethrin 50% (w/v) in a spot-on formulation, has repellent and insecticidal efficacy, against the sand fly species (*Phlebotomus papatasi*) (Mencke *et al.*, 2003), ticks (*I. ricinus, Rhipicephalus sanguineus*), and flea (*C. felis felis*) (Epe *et al.*, 2003) on dogs.

Another combination product, (Advantage Heart™ (10% w/v imidacloprid plus 1% w/v moxidectin), a macrolide antihelmintic, has been developed as a spot-on for dermal application to kittens and cats (Arther *et al.*, 2003). It is intended for monthly application for control of flea infestations and intestinal nematodes, and for prevention of feline heartworm disease. It controls and treats not only established adult gastrointestinal parasites, but also developmental stages, including fourth instar larvae and immature adults of *Toxocara cati* in cats (Hellmann *et al.*, 2003; Reinemeyer and Charles, 2003). Furthermore, the spot-on combination is safe and highly efficacious against *T. canis* and Ancylostomatidae in naturally infested dogs (Hellmann *et al.*, 2003), as well as against *Sarcoptes scabiei* var. *canis* on dogs (Fourie *et al.*, 2003).

5.3.11. Concluding Remarks and Prospects

The discovery of neonicotinoids as a new class of nAChR ligands can be considered a milestone in insecticide research, and permits an understanding of the functional properties of insect nAChRs. Up to now the most current information regarding nAChRs originated from research with vertebrate receptors. The world market for insecticides is still dominated by compounds irreversibly inhibiting acetylcholinesterase, an important enzyme in the CNS of insects. The market share of these inhibitors,

and those insecticides acting on the voltage-gated sodium channel, account for approximately 70% of the world market (Nauen and Bretschneider, 2002) (**Table 10**).

Today, the neonicotinoids are the fastest-growing group of insecticides (estimated marked share in 2005: about 15%), with widespread use in most countries in many agronomic cropping systems, especially against sucking pests but also against ectoparasitic insects. The relatively low risk and target specificity of the products, combined with their suitability for a range of application methods, also will ensure their success as important insecticides in integrated pest management (IPM) strategies.

5.4 GABA Receptors of Insects

S D Buckingham and D B Sattelle, University of Oxford, Oxford, UK

5.4.1. Introduction

Receptors for the neurotransmitter γ-aminobutyric acid (GABA) are abundant in the nervous systems of insects (Sattelle, 1990) where, as in vertebrates, they play a major role in inhibition. In 1985 when the first set of volumes of this series entitled *Comprehensive Insect Physiology, Biochemistry, and Pharmacology* was published, little was known about these proteins, despite the already established use of insect preparations to address fundamental questions in neurobiology, and despite the fact that GABA receptors (GABARs) were already considered to be possible insecticide targets. Since then, our understanding of insect GABARs has been transformed.

Since 1985, studies on GABARs have benefited from the application of molecular biology (molecular cloning, functional expression, and determination of their gene structure), electrophysiology (single-channel and whole-cell patch clamp recordings), integrative physiology (demonstrating a key role for such receptors in particular insect behaviors), genome analysis (yielding a complete set of ligand gated anion channels for the fruit fly, *Drosophila melanogaster* and the mosquito, *Anopheles gambiae*, and genetics (providing a detailed understanding of mutations that underly insecticide resistance). Radioligand binding studies have generated a detailed description of the pharmacology of insect GABAR binding sites. Electrophysiological studies, some using identified neurons, have contributed important information on GABARs, both functional native and expressed recombinant receptors. Patch clamp methods, in particular, have provided key insights, enabling: (1) the analysis of single channel properties; and (2) description of the effects of chemicals on receptor kinetics. A number of studies have examined the distribution of GABARs and other molecular components of insect GABAergic synapses using antibodies to GABA, enzymes involved in GABA synthesis, and, more recently, antibodies to cloned GABAR subunits. Thus, arange of complementary experimental approaches have led to new discoveries on the roles of GABARs in sensory receptive field tuning, learning, and even a possible role in the insect circadian clock.

A major advance in the study of insect GABARs resulted from the cloning of three candidate *Drosophila* ionotropic GABAR subunits, one of which resistant to DieLdrin(RDL) readily forms a functional, recombinant, homomeric GABA gated chloride channel. This was followed by the discovery of RDL orthologs in several insect orders. Thus, for the first time, it was possible to study in detail the physiology and pharmacology of an insect GABAR of known molecular composition. Consequently, in the years since the publication of the first edition of *Comprehensive Insect Physiology, Biochemistry and Molecular Biology*, there has been considerable growth in our understanding of insect GABARs (Hosie *et al.*,

1997) and their vertebrate counterparts (Whiting, 2003).

Insect GABAR subtypes were not well established in 1985, although even then data were beginning to emerge, to question earlier notions that benzodiazepine binding sites were not present in insects (Nielsen *et al.*, 1978). Today, we know that insect GABARs rival the complexity of their vertebrate counterparts, and possess a number of sites for modulation by not only benzodiazepines, but also several other allosteric modulators. Again, in 1985, there was no evidence for the existence of an insect metabotropic receptor – today, three candidate insect metabotropic GABARs have been cloned and their characterization is now in progress.

This chapter concentrates on new information that has accumulated since the previous edition of this series. After a brief review of findings up to 1985, we discuss the more recent findings on the physiology and pharmacology of insect ionotropic GABARs, examining each major chemical binding site in turn. Evidence for distinct subtypes of native insect GABARs is also discussed. Attention is then drawn to findings derived from the cloning and functional expression of recombinant insect GABARs, and their contributions to our understanding of (1) native receptors and (2) insecticide modes of action. Next, we consider the roles of ionotropic GABARs in insect behavior. Finally, new findings on metabotropic GABARs are described.

By 1985, GABA was already known to be an inhibitory neurotransmitter at nerve–muscle junctions and in the central nervous system (CNS) of arthropods (Kuffler and Edwards, 1958; Usherwood and Grundfest, 1965; Otsuka *et al.*, 1966), but very little is still known of insect GABARs. Most information was based on electrophysiology performed on native nerve and muscle receptors. However, GABA had been shown to induce hyperpolarizing responses in (mostly unidentified) central neurons of several insect species, including postsynaptic membranes of interneurons (Callec and Boistel, 1971; Callec, 1974; Hue *et al.*, 1979) and unidentified cell bodies (Kerkut *et al.*, 1969; Pitman and Kerkut, 1970; Walker *et al.*, 1971; Roberts *et al.*, 1981) in the terminal abdominal ganglion of the cockroach, *Periplaneta americana*. Dissociated cells of locust thoracic ganglia (Giles and Usherwood, 1985), as well as identified dorsal unpaired median neurons (DUMETi) that innervate the *Extensor tibiae* muscle of the embryonic grasshopper *Schistocerca nitens* (Goodman and Spitzer, 1980), were also found to respond to GABA with hyperpolarizations. Peripheral GABARs located on somatic muscle fibers had been described in some considerable detail (Cull-Candy and Miledi, 1981; Cull-Candy, 1982). These early studies established that GABA mediates hyperpolarizing, largely inhibitory responses in insect neurons, but other than showing a sensitivity to picrotoxinin, little was known of the details of the pharmacology of these responses.

5.4.2. Ionotropic GABARs of Insects

5.4.2.1. Lessons from Vertebrate GABARs

Our understanding of both insect and vertebrate GABARs is based on binding studies, electrophysiology of *in situ* receptors and electrophysiology of expressed recombinant receptors, each approach offering its own particular advantages. Electrophysiological responses of neurons in insect or vertebrate nervous systems as well as cultured neurons provide a detailed account of the pharmacology, ion permeability, and kinetic properties of native GABARs. It is particularly convenient where identified neurons, or classes of neurons, are studied, as the analysis is restricted to a circumscribed (in some cases, perhaps homogeneous) class of receptors. Electrophysiological studies using heterologously expressed recombinant receptors offer the further advantage that the subunit composition of the receptors is known. Binding studies complement these functional approaches. However, when applied to native tissues the technique often pools data from multiple GABARs (as well as any other binding sites for the radioligand) from all cell types in the tissue under investigation. As functional and binding experiments yield different types of information, care must be exercised when comparing data obtained using these different techniques. For example, electrophysiological and binding studies typically address different states of the same receptor, which can also contribute to some of the apparent discrepancies.

Nineteen ionotropic GABAR subunit molecules have been cloned from vertebrates (Whiting, 2003). They are members of the dicysteine-loop (cys-loop) family of ionotropic neurotransmitter receptors that also includes the nicotinic acetylcholine receptors (nAChRs) (Karlin, 2002), serotonin type 3 (5-HT_3) receptors (5HT_3Rs) (Reeves and Lummis, 2002), and strychnine sensitive glycine receptors (GlyRs) (Betz *et al.*, 1999) of vertebrates as well as glutamate gated chloride channels (GluCls), a 5-HT gated chloride channel and a histamine gated chloride channel of invertebrates (review: Raymond and Sattelle, 2002). Each receptor molecule consists of five subunits arranged symmetrically around an integral, hydrophobic ion pore (**Figure 1**). Each polypeptide

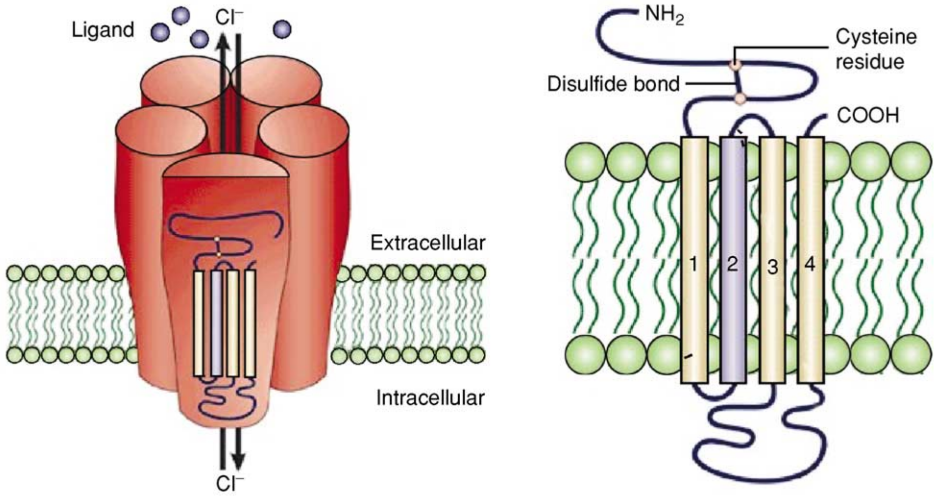

Figure 1 A schematic representation of the three-dimensional structure of ionotropic GABA receptors. Although more data are available for the structure of vertebrate ionotropic GABA receptors, it is probable that insect GABA receptors have a similar structure. (From Raymond, V., Sattelle, D.B., **2002**. Novel animal-health drug targets from ligand-gated chloride channels. *Nat. Rev. Drug Discov. 6*, 427–436.)

subunit possesses a long N-terminal extracellular domain, which contains residues that contribute to the neurotransmitter (GABA) binding site and four transmembrane regions (M1–M4) (**Figure 1**). The second transmembrane domain (M2) contains most of the residues that line the chloride channel (Karlin and Akabas, 1995; Smith and Olsen, 1995). Vertebrate ionotropic GABARs may be divided into two pharmacological categories: $GABA_A$ receptors, which are all antagonized by the alkaloid, bicuculline, and regulated by a wide range of allosteric modulators such as benzodiazepines, barbiturates, and pregnane steroids; and $GABA_C$ receptors, which are insensitive to bicuculline as well as the majority of modulators of $GABA_A$ receptors (Bormann, 2000; Zhang *et al.*, 2001). $GABA_C$ receptors are less liable to desensitize than $GABA_A$ receptors (Johnston, 1996). This physiological and pharmacological characterization is mirrored by corresponding structural differences between the two receptor subtypes, in that they are composed of distinct subunits. $GABA_A$ receptors are composed of subunits from several different classes (α_{1-6} β_{1-3} γ_{1-3}, δ, ε, π, and θ) (Hedblom and Kirkness, 1997; Thompson *et al.*, 1998; Neelands *et al.*, 1999; Bonnert *et al.*, 1999; Sinkkonen *et al.*, 2000; Whiting, 2003), whereas $GABA_C$ receptors are believed to be composed of the three known isoforms of the ρ subunit, ρ_{1-3} (Sieghart, 1995; Djamgoz, 1995; McKernan and Whiting, 1996). $GABA_A$ receptors are complex allosteric proteins and contain, in addition to the agonist binding site, distinct sites for the actions of barbiturates, steroids, loreclezole, furosemide, picrotoxin (PTX), zinc, lanthanum, volatile anaesthetics, benzodiazepines, and the anaesthetic, propofol. Although it should be noted that there is not perfect consensus on this division of vertebrate GABARs into A and C subtypes, this has been the view of the majority of workers to date and has received recent support (Bormann, 2000). This view will therefore be adopted for the purposes of this review.

Functional expression studies, in which various combinations of subunits are heterologously expressed in *Xenopus laevis* oocytes or cell lines, have shown that the pharmacology of such recombinant vertebrate receptors is strongly influenced by subunit composition. For example, the specific subtype of β subunit present is a critical determinant of agonist pharmacology, whereas the α and γ subunits are important in conferring sensitivity to benzodiazepines. When the α_1 subtype is present in the heterologously expressed receptor it exhibits a pharmacology that resembles benzodiazepine type 1 pharmacology defined on the basis of *in situ* native receptor studies. Also, the inclusion of either the α_2 or α_3 subunit confers to the receptor the classical benzodiazepine type 2 pharmacology (Pritchett *et al.*, 1989). The γ_2 subunit is essential for benzodiazepine activity (Pritchett *et al.*, 1989), and the specific subtype of γ subunit present in the receptor plays a major role in determining the receptor's responsiveness to allosteric modulators, such as benzodiazepines. Taken together, experiments using recombinant expression have suggested that native vertebrate $GABA_A$ receptors are composed of at least α, β, and γ subunits, a conclusion supported by several immunoprecipitation studies

(Mohler *et al.*, 1992; Khan *et al.*, 1994; Araujo *et al.*, 1996; Jechlinger *et al.*, 1998; Nusser *et al.*, 1999). About 35% of $GABA_A$ receptors in the brain contain $\alpha_1\beta_2\gamma_2$ subunits, 20% contain $\alpha_3\beta_3\gamma_2$, and 15% contain $\alpha_2\beta_3\gamma_2$ subunits. Other combinations are present, but they are less common (Whiting, 2003).

With fewer laboratories working in the field the growth in our knowledge of insect GABARs has been slower than that of their vertebrate counterparts. It is clear, however, that while all vertebrate and insect ionotropic GABARs are blocked by the plant derived toxin, picrotoxinin, a number of pharmacological differences distinguish insect GABARs from vertebrate $GABA_A$ and $GABA_C$ receptors. For example, insect ionotropic GABARs do not readily fit the vertebrate classification. There are two principal differences. First, the majority of insect GABARs, unlike $GABA_A$ receptors, are insensitive to bicuculline, although bicuculline sensitive insect GABARs do exist. Secondly, most insect GABARs are pharmacologically distinct from $GABA_C$ receptors in that they are subject to allosteric modulation by benzodiazepines and barbiturates (Sattelle, 1990). There are other minor differences in aspects of their detailed pharmacology, each of which will be addressed in the following sections.

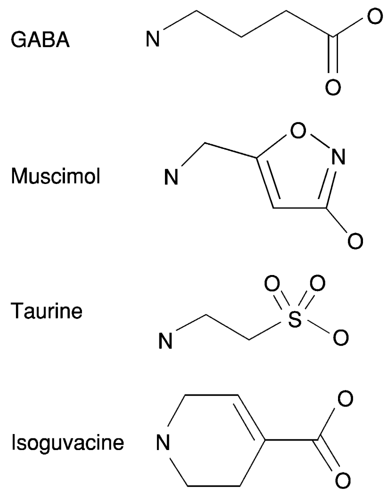

Figure 2 The molecular structures of some common agonists of vertebrate and insect ionotropic GABA receptors.

5.4.2.2. Pharmacology of *In Situ* Insect GABARs

5.4.2.2.1. Agonist site Early binding studies on cockroach (*P. americana*) nerve cord preparations using [^{3}H]GABA and [^{3}H]muscimol indicated that insect GABARs, unlike vertebrate $GABA_A$ receptors, were insensitive to 3-aminopropanesulfonic acid (3-APS). Also, muscimol is of the same, or higher, potency as GABA on insect GABARs (Lummis and Sattelle, 1985, 1986). The most potent displacers of [^{3}H]GABA binding to cockroach nerve cord preparations were found to be GABA itself and muscimol, with IC_{50}s of 130 and 710 nM respectively. In contrast, the other vertebrate agonists tested (thiomuscimol, 4,5,6,7-tetrahydroisoxazolo[5,4-c] pyridin-3-ol (THIP), 3-APS, and isoguvacine) had IC_{50}s greater than 30 mM (Lummis and Sattelle, 1986). The dissociation rate for GABA binding was estimated to be around 0.116 min^{-1} and the estimated association rate was approximately 316 $mM^{-1}\,min^{-1}$. The molecular structures of some GABAR agonists are illustrated in **Figure 2**.

Later, electrophysiological studies were performed on GABARs in an identified *Periplaneta* motor neuron (the fast coxal depressor, D_f) (Sattelle *et al.*, 1988), and on cloned *Drosophila* GABARs containing only RDL subunits heterologously expressed in oocytes or insect cell lines (Millar *et al.*, 1994; Hosie and Sattelle, 1996a, 1996b; Buckingham *et al.*, 1996). The only major difference between the [^{3}H]GABA displacement profile and the functional studies is that isoguvacine is a potent agonist on native, functional insect GABARs (Sattelle *et al.*, 1988), providing a further distinction from vertebrate GABARs. The reason for this apparent discrepancy between physiology and binding data is unclear, but may be attributable to the fact that the two methods probe different receptor states, and that the two approaches may probe different pools of receptor subtypes. The sensitivity of insect GABARs to ZAPA ((*Z*)-3-[(aminoiminomethyl)thio]prop-2-enoic acid) (Taylor *et al.*, 1993) also distinguishes them from vertebrate $GABA_A$ receptors, which are largely insensitive to this compound (Woodward *et al.*, 1993; Qian and Dowling, 1993).

Reports from several laboratories show a lack of action of established vertebrate $GABA_B$ agonists or antagonists on insect GABARs (Lees *et al.*, 1987; Sattelle *et al.*, 1988; Murphy and Wann, 1988; Bermudez *et al.*, 1991; Wolff and Wingate, 1998). However, this does not preclude the existence of $GABA_B$ receptors with unusual pharmacology. For example, the $GABA_B$R agonist baclofen and the $GABA_B$ antagonist saclofen were inactive on GABARs of D_f (Sattelle *et al.*, 1988). However, more recent experiments have identified $GABA_B$-like responses, which differ significantly in their pharmacology from vertebrate $GABA_B$ receptors in being insensitive to baclofen (Bai and Sattelle, 1995). The presence of these insect $GABA_B$ receptors was only detected when responses mediated through ionotropic GABARs were blocked by PTX.

Most insect ionotropic GABARs are relatively insensitive to the GABA analog CACA (*cis*-aminocrotonic acid), which is an agonist of vertebrate $GABA_C$, but not $GABA_A$, receptors. For example, visual interneurons in the fly, *Calliphora erythrocephala*, are CACA insensitive (Brotz and Borst, 1996). However, it should be noted that CACA activates GABARs that mediate inhibition by identified filiform hair receptors of an identified projection interneuron, a circuit that mediates wind elicited responses (Gauglitz and Pfluger, 2001).

Taurine (2-aminoethanesulfonic acid), an abundant amino acid in both vertebrates and insects, may act as a coagonist with GABA in certain insects. It is abundant in the nervous system of the locust, *Schistocerca gregaria* (Whitton *et al*., 1987), where its distribution changes following periods of intense muscular activity. When ionophoretically applied to isolated locust neurons in culture, taurine evokes membrane conductance increases very similar to those evoked by GABA (Whitton *et al*., 1994). Indeed, responses to both GABA and taurine are both blocked by PTX and enhanced by flunitrazepam, consistent with their acting through the same receptor. It was therefore suggested that taurine may act at the same site as GABA, serving to modulate the GABA response. In the migratory locust, *Locusta migratoria*, taurine is coexpressed with GABA in local and intersegmental inhibitory interneurons but not in efferent neurosecretory or paracrine cells, suggesting a role in preventing hyperexcitation during stressful conditions (Stevenson, 1999).

5.4.2.2.2. Competitive antagonists A consistent feature of most, but not all, insect GABARs is that they are insensitive to the plant derived alkaloid, bicuculline (**Figure 3**), a defining blocker of vertebrate $GABA_A$ receptors (Curtis *et al*., 1971; Watson and Girdlestone, 1995). Extrasynaptic GABARs on the motor neuron, D_f (Sattelle *et al*., 1988; Buckingham *et al*., 1994), and synaptic GABARs on the giant interneuron 2 of *P. americana* (Buckingham *et al*., 1994) are insensitive to bicuculline, as are many locust neuron ionotropic GABARs (Benson, 1988; Lees *et al*., 1987). Bicuculline does not block either the cloned *Drosophila* GABAR, RDL (Millar *et al*., 1994), or the cloned *Heliothis virescens* RDL-like GABAR (Wolff and Wingate, 1998). GABA mediated inhibitory postsynaptic potentials (IPSPs) recorded in an identified locust (*S. gregaria*) interneuron are also bicuculline insensitive (Watson and Burrows, 1987). Similarly, bicuculline insensitivity is a feature of GABARs that mediate inhibition by identified filiform hair receptors of an identified projection interneuron, a circuit that mediates wind elicited responses (Gauglitz and Pfluger, 2001). Responses to muscimol in motion sensitive visual interneurons of the fly, *C. erythrocephala*, are also insensitive to bicuculline (Brotz and Borst, 1996). Furthermore, insensitivity to bicuculline is also seen for certain spider GABARs (Panek *et al*., 2002).

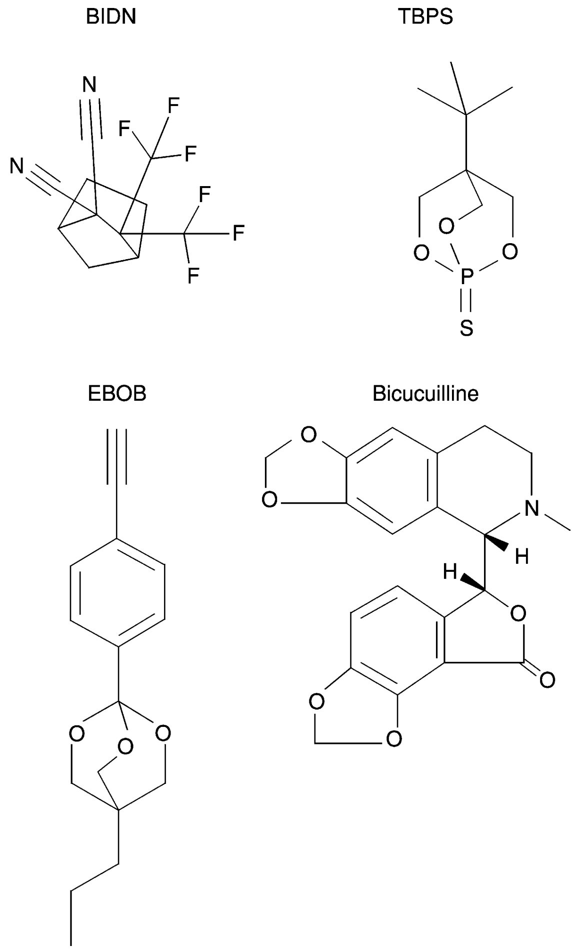

Figure 3 The molecular structures of some common convulsant antagonists of vertebrate and insect ionotropic GABA receptors.

However, there is a body of evidence that bicuculline does block ionotropic GABARs of some adult *Manduca sexta* abdominal ganglion neurons (Roberts *et al*., 1981; Waldrop *et al*., 1987; Waldrop 1994) as well as electrically or odor evoked IPSPs and GABA responses in projection neurons of antennal lobes of this species (Christensen *et al*., 1998). Recently, Sattelle *et al.* (2003) have also shown that bicuculline insensitive GABARs are present in the larval nervous system of *M. sexta*. Further, the observation that bicuculline is effective in recovering behaviors disrupted by the systemic administration of GABA transporter blockers (Leal and Neckameyer, 2002) suggests that, despite the lack of bicuculline action on RDL, bicuculline

may nonetheless block some *D. melanogaster* GABARs. In addition, bicuculline also blocks certain nicotinic acetylcholine receptors (nAChRs) of insects (Benson, 1988; Buckingham *et al*., 1994) and vertebrates (Rothlin *et al*., 1999).

One attempt to resolve the issue of bicuculline sensitivity tested the possibility that such divergent reports may reflect pharmacological differences between extrasynaptic and synaptic GABARs (Buckingham *et al*., 1994). The cockroach, *P. americana*, offers a convenient model for such an approach because of the number of indentified neurons with ready access to both their cell bodies and their synapses. Motor neuron D_f has a population of well-characterized GABARs on its cell body membrane, and giant interneuron 2 (GI 2) not only presents an accessible cell body, but also receives synaptic inputs from nerve X. IPSPs measured in GI 2 using the oil gap recording method in response to electrical stimulation of nerve X were blocked by both bicuculline (100 μM) and PTX (0.01 μM). However, bicuculline injected directly into the neuropil in the region of these synapses did not block IPSPs. The apparent block of synaptic GABARs by bicuculline was found to be due to inhibition of nAChRs upstream in the synaptic pathway. While the study failed to find differences in the pharmacology of synaptic and extrasynaptic GABARs, it did show that three separate populations of GABARs exist: synaptic receptors in the neuropilar branches of GI 2, extrasynaptic GABARs on the cell body of GI 2, and extrasynaptic GABARs on D_f, all of which are bicuculline insensitive. The finding that bicuculline acts on nAChRs does not, however, explain the block of IPSPs by bicuculline in *M. sexta* interneurons (Waldrop *et al*., 1987), since ACh responses in this preparation are insensitive to direct bicuculline application (Waldrop and Hildebrand, 1988).

Thus, there is some crossover between the pharmacophore for ligand binding sites of insect ionotropic GABARs and nAChRs. Whereas most insect GABARs are insensitive to bicuculline, many insect ACh receptors, in contrast, are blocked by bicuculline (Buckingham *et al*., 1994; Waldrop, 1994). At the same time, imidacloprid, an insecticide acting as a partial agonist of nAChRs, can also partially block GABARs of honeybee Kenyon cells, albeit at relatively high concentrations (Deglise *et al*., 2002).

In addition to their abundant expression in the CNS, and in contrast to vertebrates, insect GABARs are also expressed on muscle fibers. In many respects, these muscle insect GABARs resemble those of the nervous system in that they are sensitive to muscimol and to the GABA channel blocker, picrotoxinin (Scott and Duce, 1987; Murphy and Wann, 1988). However, until 1997, no detailed comparison had been reported for muscle and neuronal GABARs in the same animal for any insect species. One study, therefore, set out directly to compare GABARs on fibers of the coxal levator muscle (182c,d) of the cockroach, *P. americana* (Schnee *et al*., 1997), with the well-characterized GABARs on the motor neuron, D_f, of the same species (Sattelle *et al*., 1988). Both were sensitive to PTX and insensitive to bicuculline, but there were significant pharmacological differences between them. Unlike the neuronal receptors, the muscle GABARs were insensitive to isoguvacine. The EC_{50} of muscimol relative to GABA was also much lower for muscle than for D_f. The muscle GABARs were also sensitive to certain cyclodienes: 12-ketoendrin, endrin, and heptachlor epoxide all reduced GABA responses with IC_{50}s in the 1–10 nM range. Similarly, micromolar concentrations of the cyclodiene, heptachlor, produced a complete block of muscle receptors, whereas concentrations as high as 100 μM resulted in about 50% block of GABARs on cockroach motor neuron D_f (Lummis *et al*., 1990). Micromolar *tert*-butyl-bicyclo[2.2.2]phosbrothionate (TBPS) and tert-butyl-bicylo orthobenzoate (TBOB) were almost without effect on muscle receptors. Hence, in the cockroach there are some clear differences between neuronal and muscle GABARs. The observation that muscle GABARs are significantly more sensitive to cyclodienes than the GABARs of motor neuron D_f is interesting in view of the fact that mutants of RDL are resistant to cyclodienes, yet RDL is expressed exclusively in the nervous system. This discrepancy remains to be addressed.

5.4.2.2.3. Noncompetitive antagonists and convulsants Several convulsants (**Figure 3**) are noncompetitive antagonists of insect GABARs and this site is the target of many insecticides, including the cyclodienes (such as endrin, dieldrin), hexachlorocyclohexanes (such as lindane), and bicycloorthobenzoates (such as 1-(4-ethynylphenyl)4-*n*-propyl-2,6,7-trioxabicyclo[2.2.2]octane (EBOB)) (Matsumura and Ghiasuddin, 1983; Lummis and Sattelle, 1986; Wafford *et al*., 1989; Lummis *et al*., 1990; Deng *et al*., 1993; Anthony *et al*., 1994). The earliest evidence that cyclodienes act at the convulsant site came from binding studies using [^{3}H]dihydropicrotoxinin, which indicated that the cyclodiene and PTX binding sites were similar (Matsumura and Ghiasuddin, 1983). Further, houseflies resistant to dieldrin show cross-resistance to many polychlorocycloalkanes and phenylpyrazoles, and to some bicycloorthobenzoates, but not to avermectins

(Deng *et al.*, 1991; Deng and Casida 1992; Cole *et al.*, 1993; Casida, 1993).

Initial studies using labeled probes for the convulsant site were hampered by the limitations of [^{3}H]dihydropicrotoxinin as a probe. These were largely overcome as improved radioligands became available. Specific, saturable binding of [^{35}S]TBPS to cockroach nerve cord membranes yielded a K_d of around 18 nM and B_{max} of around 177 fmol mg^{-1} protein (Lummis and Sattelle, 1986). This binding was inhibited by GABA and dihydroavermectin B_{1a} at micromolar concentrations, suggesting the presence of an allosteric linkage between these sites in insect GABARs.

Radioligand binding and toxicity approaches used by John Casida's laboratory have been particularly fruitful not only in identifying the sites of action of many insecticidally relevant compounds, but also in providing a pharmacological dissection of the convulsant site. The [^{3}H]EBOB binding site of housefly heads was found to be identical to, or to overlap with, a wide array of structurally distinct insecticides (Deng *et al.*, 1991) including cyclodienes, bicycloorthobenzoates, and PTX, but not avermectins. This was pursued further in a comprehensive study of the convulsant site examining the displacement of labeled EBOB and TBPS by 29 different compounds (Deng *et al.*, 1993). Binding of [^{35}S]TBPS to housefly head membranes had a K_d of 145 nM and B_{max} of 2.4 pmol mg^{-1} protein, and both [^{35}S]TBPS and [^{3}H]EBOB were displaced by a number of polychlorocycloalkanes, bicycloorthobenzoates, and phenylpyrazoles. The binding parameters resembled those of vertebrate tissues with respect to pH dependence, anion specificity and kinetics of association, and dissociation. Comparing the modes of competition of each compound class (i.e., competitive versus noncompetitive) and their relevance to toxicity, this study concluded that four subsites can be defined pharmacologically: site A (the EBOB site) overlaps with site C (the phenylpyrazole site) and with site B (the TBPS site), but sites B and C do not overlap. The avermectin site (site D) is distinct from all of the other three sites, but is allosterically linked to sites A and C.

Similar studies added weight to the conclusion that insect GABARs differ significantly from their vertebrate counterparts at the noncompetitive binding sites. For instance, they are significantly less sensitive to the polychlorocycloalkane, cage convulsants (such as TBPS and TBOB), and PTX, compounds that by contrast are potent inhibitors of vertebrate GABARs (Rauh *et al.*, 1990). A single exception to this rule is furnished by the polychlorocyclohexane insecticide, heptachlor, and its epoxide metabolite, which more potently displaced labeled TBPS from *Musca domestica* membranes than from rat (Lummis *et al.*, 1990). However, when muscle GABARs of the cockroach, *P. americana*, were compared to those on an identified motor neuron of the same species (Schnee *et al.*, 1997), muscle GABARs were found to be more sensitive to lindane and to heptachlor and its epoxide metabolite.

One fertile approach to understanding the convulsant site has been to compare the efficacies of a systematically varying set of PTX analogs in either blocking the receptor or in displacing radiolabeled probes. Such studies on vertebrate tissues led to the proposal (Ozoe and Matsumura, 1986) that the key elements in determining picrotoxane activity are the presence of a bulky lipophilic group and at least two electronegative centers. Several studies have emphasized the importance of two groups in the PTX molecule (the hydroxyl and the isopropenyl groups) in conferring high lethality (Jarboe *et al.*, 1968), on displacing [^{3}H]-dihydropicrotoxin (Ticku *et al.*, 1978), and as well as affecting electrophysiological responses of *in situ* (Kudo *et al.*, 1984) and recombinant GABARs (Anthony *et al.*, 1993). These conclusions were drawn in particular from the observation that fluoropicrotoxinin, which substitutes a fluorine at the hydroxyl position, is almost equally active as the parent molecule, whereas PTX acetate is much reduced in potency, and that picrotin, which adds a hydroxyl group to the isopropenyl, is also comparatively ineffective. Such findings suggest that for vertebrates, the hydroxyl group may act as a hydrogen bond acceptor, that substitutions at the hydroxyl group are liable to steric hindrance, and that the isopropenyl group must be lipophilic or electron-rich (Anthony *et al.*, 1993) for maximal activity. To determine whether the same is true for insect GABARs, one study (Anthony *et al.*, 1994) examined the actions of a series of PTX analogs on the well-defined GABARs on the identified motor neuron, D_f, of the cockroach, *P. americana*. The rank order of potency was the same as for expressed chick optic lobe GABARs, suggesting that the convulsant sites of insect and vertebrate $GABA_A$ receptors share certain common key features. Similar findings were obtained for RDL, a cloned insect GABAR (see Section 5.4.2.4.3.2).

The reduced sensitivity of insect GABARs to TBPS slowed the development of our understanding of insect convulsant site probes. Recently, however, two compounds have been deployed with selectivity for insect over vertebrate GABARs, BIDN, and fipronil (**Figures 3 and 4**).

BIDN ([^{3}H]3,3-bis-trifluoromethyl-bicyclo[2,2,1] heptane-2,2-dicarbonitrile) was developed using a

combined biochemical and pharmacophore modeling approach (Rauh *et al*., 1997a, 1997b). A large library of compounds was systematically screened for their ability to displace [^{35}S]TBPS from rat brain membranes. Several bicyclic dinitriles were identified and further screened for their selectiviy for insect GABARs over rat GABARs. This approach identified the common structural features of known convulsant site ligands, which helped to determine the key pharmacophore features (**Figure 5**) This was done by manually aligning each of a series of polycyclic dinitriles over a representation of the PTX molecule using the Sybyl software package (SYBYL Molecular Modeling Software, Tripos Associates, Inc., St. Louis, MO). Key pharmacophore elements identified were the presence of a polarizable moiety separated by a fixed distance from two hydrogen bond-accepting (i.e., electronegative) elements (**Figure 5**), confirming and extending the model proposed earlier by Ozoe and Matsumura (1986). A number of new potential ligands were developed from this pharmacophore model. Of these, the most useful was BIDN (Rauh *et al*., 1997a, 1997b).

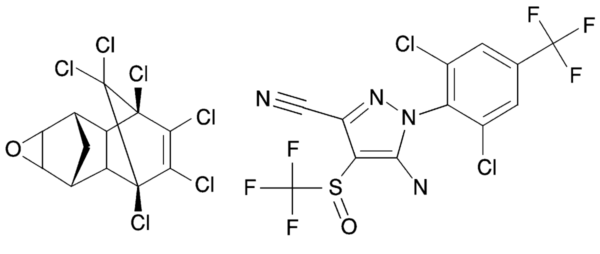

Figure 4 The molecular structures of two potent antagonists of insect ionotropic GABA receptors, dieldrin and fipronil, both of which have been used as insecticides.

Binding of [^{3}H]BIDN to southern corn rootworm (*Diabrotica undecimpunctata*) membranes was saturable and specific with high affinity (26 nM) and a Hill coefficient of unity suggesting that BIDN binds to a single class of receptor sites (Rauh *et al*., 1997b). Such high-affinity, specific binding was confirmed in the same study for five other insect species, including *P. americana* and *M. domestica*, whereas binding of BIDN to rat membranes was of lower affinity (around 250 nM). The same study examined the actions of BIDN using electrophysiological techniques, which showed that BIDN blocks GABARs of the identified cockroach motor neuron D_f as well as those present on the coxal levator muscles of the same species. BIDN also blocks GABA evoked depolarizations of thoracic neurons in the southern corn rootworm, (Rauh *et al*., 1997b). The estimated IC_{50} for BIDN action against central (on the cell body of motor neuron, D_f) and peripheral (on coxal levator muscle fibers) GABARs of *P. americana* was 0.9 μM and 2.5 μM, respectively. Although showing a degree of selectivity for insect over vertebrate receptors, the vertebrate toxicity of BIDN was a factor precluding its further development as a commercial pesticide.

Another insect GABAR ligand is the potent, widely used insecticide active on insect GABARs, the phenyl pyrazole, fipronil. Fipronil is a potent antagonist of cloned insect GABARs (Hosie *et al*., 1997; Grolleau and Sattelle, 2000) and has also been used as the basis for the development of a photo-affinity probe for the convulsant site (Sirisoma *et al*., 2001). There is abundant evidence that BIDN and fipronil act at the convulsant site. Fipronil competes for EBOB binding to housefly head membranes (Ratra and Casida, 2001). BIDN (Hosie *et al*., 1995b), picrotoxinin (Shirai *et al*., 1995), and fipronil (Hosie

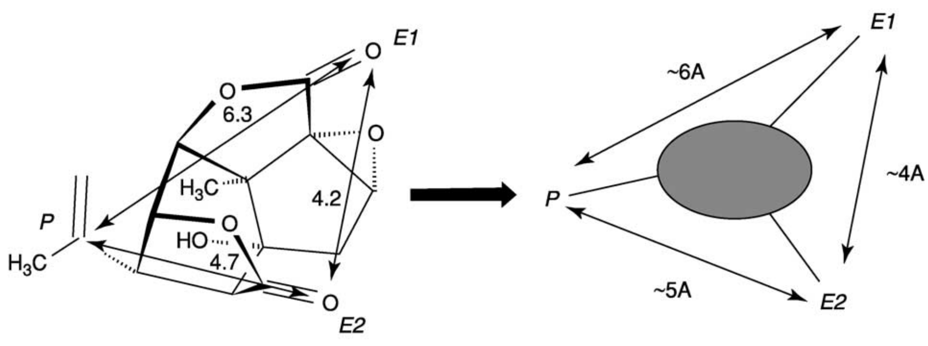

Figure 5 The ideal pharmacophore for the picrotoxin molecule. This was derived from a number of structure–function studies that have revealed the structural features that confer potency to picrotoxin analogs. This was used to predict that a series of bicyclic dinitriles would have potency at the picrotoxinin site. (From Rauh, J.J., Holyoke, C.W., Kleier, D.A., Presnail, J.K., Benner, E.A., *et al*., **1997b**. Polycyclic dinitriles: a novel class of potent GABAergic insecticides provides a new radioligand, [^{3}H]BIDN. *Invert. Neurosci. 3*, 261–268.)

et al., 1995b) all block RDL (see below) in a voltage independent, partly competitive and partly noncompetitive manner. However, although dieldrin displaces [^{3}H]BIDN binding competitively, PTX does not (Sattelle *et al.*, 1995), suggesting that the PTX and the dieldrin site are not identical. This confirms an earlier report (Deng *et al.*, 1993) that identified no less than four convulsant antagonist binding sites in the housefly GABAR that can be differentiated by [^{3}H]EBOB and [^{35}S]TBPS. It is therefore likely that BIDN, fipronil, EBOB, and PTX act at distinct but overlapping sites. Together, these compounds therefore provide a powerful tool-kit with which to further dissect the actions of insecticides on GABARs. Single channel properties of RDL expressed in a *Drosophila* cell line suggested that BIDN and fipronil both reduce the mean open time of GABAR chloride channels, but do so by acting at distinct sites (Grolleau and Sattelle, 2000) – see Section 5.4.2.4.3.2.

There are no doubt a number of naturally occurring ligands with GABAergic actions that await discovery. An interesting class of compounds acting at this site is the α and β thujones, the active ingredients of absinthe and present in certain herbal medicines. These compounds act at the convulsant site to block GABARs noncompetitively, and have insecticidal activity (Hold *et al.*, 2000, 2001). It will be of interest to study possible actions of other plant derived compounds on insect GABARs.

5.4.2.2.4. Allosteric modulators

5.4.2.2.4.1. Benzodiazepines In 1985, there was still some controversy as to whether insect nervous tissues possess receptors for benzodiazepines. One report suggested a lack of benzodiazepine receptors in invertebrates (Neilsen *et al.*, 1978) but this was followed by a number of reports (Abalis *et al.*, 1983; Lummis and Sattelle, 1986; Robinson *et al.*, 1985) of sensitivity of insect GABARs to benzodiazepines. All these reports indicated that the pharmacology of the insect benzodiazepine site differs from most of its vertebrate counterparts. Specific [^{3}H]flunitrazepam binding to cockroach (*P. americana*) nerve cord membranes yielded an estimated K_d of 383 nM and B_{max} of 5.5 pmol mg^{-1} protein (Lummis and Sattelle, 1986). The most potent displacer of this binding was Ro5-4864 ($IC_{50} = 1\,\mu M$), which was only slightly more potent than flunitrazepam ($IC_{50} = 1.6\,\mu M$). Clonezapam was much less effective ($IC_{50} = 25\,\mu M$). The pharmacological profile of the [^{3}H]flunitrazepam binding site in *P. americana* was Ro5-4864 ($IC_{50} = 0.6\,\mu M$) > diazepam ($IC_{50} = 1.0\,\mu M$) > flunitrazepam ($IC_{50} = 1.6\,\mu M$) ≫ clonazepam ($IC_{50} = 25\,\mu M$) ≫ Ro15-1788 ($IC_{50} = 100\,\mu M$). Allosteric linkage between the agonist and benzodiazepine sites was confirmed by the fact that 0.1 mM GABA enhanced flunitrazepam binding by some 150%. Furthermore, flunitrazepam enhanced responses to GABA in locust neuronal somata (Lees *et al.*, 1987; Whitton *et al.*, 1994) and in the motor neuron D_f of the cockroach at micromolar concentrations (Sattelle *et al.*, 1988). The mode of action of benzodiazepines seems to be, as in vertebrates, an increase in the frequency of opening of the GABA gated channel (Shimahara *et al.*, 1987).

The potent displacement of [^{3}H]flunitrazepam binding in cockroach by Ro5-4864 and its potentiation of GABA responses suggests that cockroach CNS benzodiazepine receptors resemble vertebrate peripheral benzodiazepine binding sites rather than central ones (Lummis and Sattelle, 1986). These peripheral binding sites in vertebrates are located principally in the kidney and liver, where they are associated with calcium channels. Nevertheless, the observation that flunitrazepam and GABA binding are allosterically linked, along with physiological evidence discussed below, confirm that the [^{3}H]flunitrazepam binding site in insect CNS is indeed part of a GABAR.

Flunitrazepam and diazepam have no effect upon GABARs of coxal levator muscle of cockroach, even at concentrations of up to 100 μM (Schnee *et al.*, 1997) or upon the cloned *H. virescens* GABAR (Wolff and Wingate, 1998). Flunitrazepam does, however, evoke responses to GABA in the cockroach D_f motor neuron (Sattelle *et al.*, 1988) and other neuronal preparations (review: Sattelle, 1990). That there are differing accounts of the actions of benzodiazepines upon insect GABARs is not surprising, given the great diversity in benzodiazepine pharmacology of vertebrate GABARs and the acute sensitivity of its pharmacology on subunit composition. A sensitivity to Ro5-4864 is probably the most significant distinguishing feature since the site of action of this compound in vertebrates is not on GABARs. Further, the lack of evidence for actions of benzodiazepines on insect muscle GABARs may represent an additional distinction between muscle and neuronal GABAR subtypes in insects, although more benzodiazepines would have to be tested to confirm this hypothesis.

5.4.2.2.4.2. Barbiturates Although there have been relatively few studies, there is evidence that insect GABARs possess a site for the action of barbiturates. Enhancement of responses to GABA recorded in locust neurons by barbiturates has been reported (Lees *et al.*, 1987), and phenobarbital enhances responses mediated by the heterologously expressed *H. virescens* GABAR (Wolff and Wingate, 1998). In contrast, sodium pentobarbital at 100 μM failed to modify

responses to GABA recorded in cockroach coxal levator muscle (Schnee *et al.*, 1997).

5.4.2.2.4.3. Other allosteric modulators In addition to the benzodiazepine and barbiturate allosteric modulator sites, there are reports of modulatory actions of other compounds. Pregnane steroids displace [^{35}S]TBPS binding from *M. domestica* membranes, but with low affinity, while the insect steroids ecdysone and 20-hydroxyecdysone are almost without effect (Rauh *et al.*, 1990). Other allosteric modulators of insect GABARs include thymol (Gonzalez-Coloma *et al.*, 2002). Priestley *et al.* (2003) have shown that thymol acts at a novel allosteric site. Propofol, widely used as an anaesthetic, enhances GABA responses mediated through RDL by up to about nine-fold with an EC_{50} of about 8 μM (Pistis *et al.*, 1996a). The action of propofol on vertebrate $GABA_A$ receptors is critically dependent upon the presence of a specific amino acid in the second transmembrane domain of the receptor (Pistis *et al.*, 1999).

5.4.2.3. Diversity: Existence of Subtypes

One of the most convincing demonstrations of the existence of multiple GABAR subtypes is provided where different tissues within the same animal possess receptors of distinct pharmacology. Bicuculline sensitive and insensitive GABARs are present in the nervous system of the moth, *M. sexta* (Waldrop, 1994; Waldrop *et al.*, 1987a,b; Sattelle *et al.*, 2003). In *P. americana*, muscle receptors differ from nervous system receptors in their insensitivity to isoguvacine and higher sensitivity to channel blockers, along with differences in their sensitivity to barbiturates and benzodiazepines, although the latter is less likely to be useful in defining the muscle subtype given the wide variation in benzodiazepine pharmacology among different GABARs. Taken together, however, the differences in pharmacology between insect muscle and neuronal receptors is sufficient to justify considering them as distinct receptor subtypes.

An even more convincing demonstration of the existence of GABAR subtypes is furnished where two types of GABARs can be demonstrated on the same cells. Here, work on identified cells is particularly compelling. DUM (dorsal unpaired median) neurons of the cockroach have been shown to possess at least two subtypes of ionotropic GABAR, one of which is regulated by intracellular calcium ions through a calmodulin pathway, while the other is sensitive to CACA but seemingly not regulated by intracellular calcium (Alix *et al.*, 2002).

Clearly, not only are insect GABARs to be distinguished pharmacologically from the major vertebrate subtypes, but there is also considerable evidence to suggest that insect GABARs are not of one pharmacologically uniform type. However, there is not enough data available yet to group all the known insect GABARs into a clearly delimited classification scheme. We would argue, however, that a classification into bicuculline sensitive versus insensitive and a subset of bicuculline insensitive muscle receptors is justified on the basis of currently available evidence.

5.4.2.4. Molecular Biology

5.4.2.4.1. Cloned receptors Ionotropic GABAR subunits have been cloned from eight species of insect. These fall into three distinct types: RDL, which has been found in a number of insect species, and lignad-gated chloride channel 3 (LCCH3) and GABAA and glycine receptor-like subunit of *Drosophila* (GRD), which are only known to date in *Drosophila*. All three are structurally similar to vertebrate $GABA_A$ receptor subtypes, and more generally to the cys-loop family of neurotransmitter receptors: they have four transmembrane domains of which the second possesses an amphipathic helix and a dicysteine motif in the extracellular domain (see Hosie *et al.*, 1997). GRD resembles both ionotropic GABA and glycine receptors of vertebrates (Harvey *et al.*, 1994). It has 33–44% identity to vertebrate GABAR subunits, but is distinguished by a large insertion between the dicysteine loop and the first transmembrane spanning region. Such a feature is not seen in any other ligand gated chloride channel. Its highest sequence identity is to vertebrate $GABA_A$ α subunits (40–44% identity), but it has almost the same degree of sequence identity to vertebrate glycine receptor α subunits (40–41% identity). GRD does not form receptors in *Xenopus* oocytes, but its presumed M2 region contains seven of the eight amino acid motif (TTVLTMTT) that is a signature of ligand gated chloride channels (Harvey *et al.*, 1994). Furthermore, *Xenopus* oocytes, injected with mRNA encoding the GRD subunit, do not respond to a wide range of amino acids and glutamate receptor agonists, neither does GRD form functioning receptors when coinjected with bovine $GABA_A$ α1 or β1 subunit or rat glycine β subunits (Harvey *et al.*, 1994). In light of the failure of GRD to support GABA responses, it is probably significant that GRD lacks any equivalent to the ligand binding domain II (TGSY) of $GABA_A$ receptors. There is, therefore, reason to suspect that GRD may not even be a GABAR subunit. LCCH3 has

high (approximately 47%) identity to vertebrate $GABA_A$ β subunits (Henderson *et al*., 1993, 1994).

5.4.2.4.2. RDL: a model insect ionotropic GABAR The *rdl* (resistance to dieldrin) gene was originally isolated from a naturally occurring dieldrin resistant strain of *D. melanogaster* (ffrench-Constant *et al*., 1991, 1993a). The *rdl* locus maps to position 66F of chromosome III. It has nine exons, alternative splicing of two of which gives rise to four gene products (**Figure 6**), of which the most extensively studied are RDLac and RDLdb. The *rdl* gene is not limited to *Drosophila*, nor indeed even to the Diptera. RDL-like GABAR subunits with 85–99% amino acid identity have also been cloned from *Myzus persicae* (Anthony *et al*., 1998), *H. virescens* (Wolff and Wingate, 1998), *Aedes aegypti* (Thompson *et al*., 1993a), *Drosophila simulans* (ffrench-Constant *et al*., 1993a), *M. domestica* (Thompson *et al*., 1993a), *Blatella germanica* (Thompson *et al*., 1993b; Kaku and Matsumura, 1994), *Tribolium castaneum* (Miyazaki *et al*., 1995), and *Hypothenemus hampei* (Andreev *et al*., 1994), indicating that it is widespread throughout insect orders. The RDL polypeptide has between 30% and 38% identity with vertebrate GABAR subunits (about the same identity among different vertebrate subunit types).

RDL GABAR subunits encoded by the *rdl*gene are distributed throughout the adult (Harrison *et al*., 1996) and embryonic (Aronstein and ffrench-Constant, 1995) nervous system of *Drosophila*, particularly in the optic lobes, ellipsoid body, fan-shaped body, ventrolateral cerebrum, and glomeruli of antennal lobes. RDL is not expressed in muscle. Furthermore, in *Drosophila*, RDL expression is largely confined to the neuropil, with no discernible expression on neuronal cell body membranes or muscle (Harrison *et al*., 1996), although cell bodies were clearly stained in *P. americana* (Sattelle *et al*.,

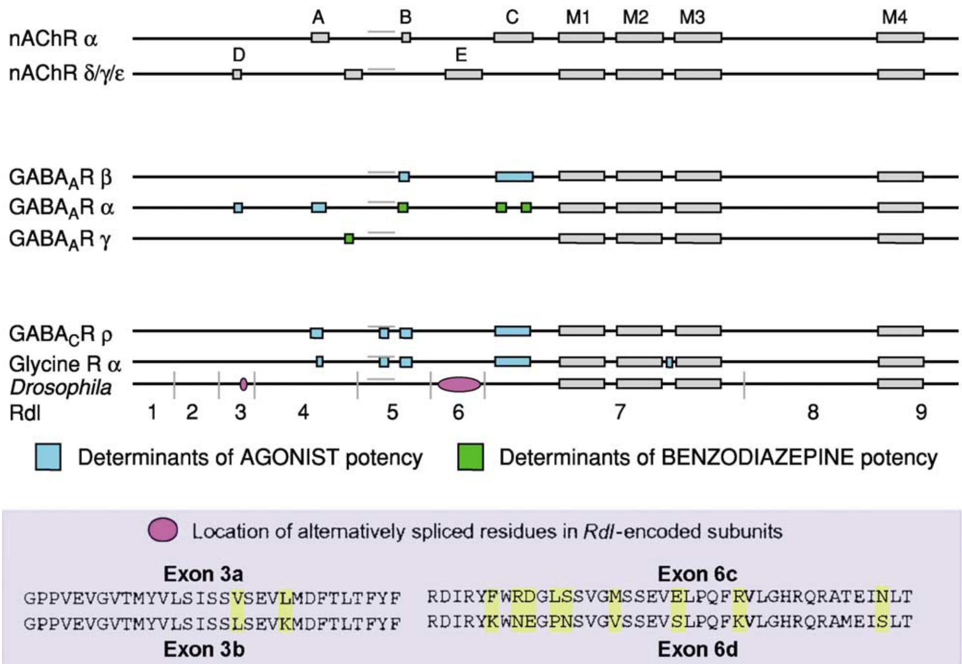

Figure 6 The locations of the determinants of agonist potency of cys-loop receptors are highly conserved. In this schematic alignment of cys-loop receptor subunits, the location of the cysteine-loop is indicated by the line above the subunit. The location of known determinants of agonist potency in nACh receptors, termed loops A–E, are marked yellow, while those of benzodiazepine potency are marked green. The exon boundaries of Rdl-encoded polypeptides are marked by vertical red lines. As a result of the alternative splicing of two exons, the *Drosophila* Rdl gene encodes four polypeptides, each of which exhibits characteristic features of $GABA_A$ receptor subunits. The alternatively spliced exons (3 and 6) encode regions of the extracellular N-terminal domain. There are two variant forms of each exon; those of exon 3 are termed ''a'' and ''b'' and differ by two residues, while the alternate forms of exon 6, termed ''c'' and ''d'', differ at 10 residues. Thus, depending on the splice variants present in a given polypeptide, the different Rdl encoded subunits may be referred to as RDL_{ac}, RDL_{bd}, etc. mRNAs encoding all four splice variants have been identified in embryonic *D. melanogaster*. The positions of these variant residues are marked in purple. The two alternate residues encoded by exon 3 lie close to a known determinant of the agonist potency of GABA receptors, while the 10 variant residues encoded by splice variants of exon 6 span a region that is poorly conserved in vertebrate GABA receptor subunits, but which corresponds to determinants of agonist potency in nAChRs. (Reproduced with permission from Hosie, A.M., Aronstein, K., Sattelle, D.B., ffrench-Constant, R.H., **1997**. Molecular biology of insect neuronal GABA receptors. *Trends Neurosci. 20*, 578–583.)

2000) and *Acheta domesticus* (Strambi *et al.*, 1998). RDL is very strongly expressed (Harrison *et al.*, 1996), where the pattern of staining is compartmentalized, suggesting that some, but not all, Kenyon cells (the principal interneurons of the mushroom bodies) receive GABAergic inputs (Brotz *et al.*, 1997). The significance of this pattern of expression is discussed in the following section. The distribution of RDL staining corresponds closely to staining for glutamic acid decarboxylase (GAD; the enzyme involved in the synthesis of GABA) (Buchner *et al.*, 1988), GABA, and synaptotagmin (DiAntonio *et al.*, 1993), suggesting that they contribute to the formation of synaptic receptors. Similar patterns of distribution in the mushroom bodies have been observed in the case of the cockroach *P. americana* (Sattelle *et al.*, 2000) and the cricket *A. domesticus* (Strambi *et al.*, 1998), where again RDL distribution closely matched GABA staining, although details of the pattern of staining differed somewhat across different species.

When expressed in *Xenopus* oocytes, RDL forms receptors (presumably homomeric, as no endogenous GABAR subunits have been reported in these cells) that respond to GABA with thresholds around 1–10 μM (ffrench-Constant *et al.*, 1993a, 1993b; Hosie *et al.*, 1995a, 1995b) as well as in baculovirus transfected sf9 cells (Lee *et al.*, 1994) and a *Drosophila* S2 cell line (Millar *et al.*, 1994). These currents reverse close to the equilibrium potential for chloride ions. Responses are dose-dependent and there is little evidence of rapid (<20 s) desensitization. The responses to GABA are very robust, often in the microampere range (ffrench-Constant *et al.*, 1993a, 1993b). The stable, inducible expression of RDL in the S2-RDL *Drosophila* cell line is particularly convenient: it allows long-term maintenance of a cell line expressing insect GABARs of known molecular composition, facilitating single channel kinetic analysis of ligand–receptor interactions. Both wild-type and mutant (RDL A302S) receptors have been expressed in these cell lines (Lee *et al.*, 1994; Millar *et al.*, 1994).

5.4.2.4.2.1. Comparison of RDL with* in situ *GABARs of insects Currently there is little information on *Drosophila* native GABARs with which to compare the pharmacology or physiology of recombinant RDL receptors. However, it has been shown that GABA responses of *Drosophila* motor neurons reverse around the resting potential and are blocked by PTX (Rohrbough and Broadie, 2002). Neurons cultured from embryonic *Drosophila* form synapses with one another, which include GABAergic synapses (Lee and O'Dowd, 1999). More recently, GABAergic synapses between embryonic *Drosophila* neurons have been shown to be PTX-sensitive, and this sensitivity is reduced in neurons derived from the dieldrin insensitive mutant strain (Lee *et al.*, 2003), suggesting that these synaptic connections involve RDL. Also, *Drosophila* CNS midline precursors in culture show responses to GABA (Schmidt *et al.*, 2000). Similarly, GABA gated currents of cultured *Drosophila* neurons are also blocked by PTX but are insensitive to bicuculline (Zhang *et al.*, 1994). Thus, what little is known of *Drosophila* GABARs *in situ* suggests that they resemble typical bicuculline insensitive insect GABARs.

5.4.2.4.3. Pharmacology of heterologously expressed RDL

5.4.2.4.3.1. The agonist site RDL of *D. melanogaster*, and its equivalent from the mosquito, *Aedes aegypti*, form functional homomers when expressed in *Xenopus* oocytes (ffrench-Constant *et al.*, 1993a, 1993b; Hosie *et al.*, 1996; Shotkoski *et al.*, 1994) as well as when stably expressed in a *Drosophila* cell line (Millar *et al.*, 1994). *Drosophila melanogaster* RDL expressed in *Xenopus* oocytes has a rank order of agonist potency of muscimol = GABA = TACA > CACA ≫ glycine (Hosie *et al.*, 1995a, 1995b). Similarly, the rank order of potency of agonists acting on RDL stably expressed in an insect cell line is GABA = TACA > CACA ≫ glycine = taurine (Buckingham *et al.*, 1996). The lack of activity of glycine is of interest, since the amino acid sequence of RDL more closely resembles that of glycine receptors than it does of many GABAR subunits (ffrench-Constant and Rocheleau, 1992). RDL is also insensitive to 3-APS yet is activated by isoguvacine (Hosie and Sattelle, 1996a). The high potency of muscimol (**Figure 2**), the sensitivity of RDL to CACA and isoguvacine, along with its insensitivity to 3-APS, are all features characteristic of insect nervous system GABARs, but not of insect muscle (see above). This supports the observation that RDL is widely expressed in the nervous system but not in muscle.

An interesting set of findings resulting from a chance observation of atypical agonist induced currents in RDL led to the discovery of the strong pH sensitivity of RDL. The GABA agonists THIP (4,5,6,7-tetrahydroisoxazolo[5,4-c]pyridin-3-ol) and ZAPA (*Z*-3-[(aminoiminomethyl)thio]prop-2-enoic acid) appeared to lead to a desensitizing response, followed by a pronounced "off" response upon agonist washout (Matsuda *et al.*, 1996). Further investigation showed this to be the result of acidification of the test saline by the agonists. When this was corrected, more typical responses were observed.

What is particularly significant about this, however, is that the apparent off response was due to a pH dependency of the efficacy of these two compounds–preacification of the saline greatly reduced the amplitude of the responses to these agonists. The actions of other agonists tested on RDL, including GABA, were pH independent. Other studies had shown that protonation of histidine residues underlies pH dependent actions of GABA on recombinant mammalian receptors (Krishek *et al*., 1996), as well as the pH dependency of the action of zinc ions (Wang *et al*., 1995). This points to further differences between the agonist binding sites of RDL and vertebrate $GABA_A$ receptors. From the pKa of GABA and THIP at the pH of the uncorrected test solutions (about 4.5), about 76% of the hydroxyls of GABA would be dissociated and about 50% of the hydroxyls of THIP would be dissociated. Thus, some of the differences in pH sensitivity of these drugs may be due to the importance of the dissociated state of the acidic group in ligand binding. Alternatively, these differences may also be attributable to pH dependent states of the histidine residues that form part of the receptor. There are seven histidine residues in the extracellar N-terminal of RDL, and future studies of the effects of point mutations involving each of these residues may help uncover new insights into the agonist actions on RDL.

Another key feature in which RDL resembles *in situ* insect GABARs is its insensitivity to bicuculline. This insensitivity to bicuculline is seen whether RDL is expressed transiently in *Xenopus* oocytes (Hosie and Sattelle, 1996a) or stably expressed in a *Drosophila* cell line (Millar *et al*., 1994). Bicuculline insensitivity is a feature also possessed by the *rdl* gene cloned from *H. virescens* (Wolff and Wingate, 1998). Since, as argued above, most insect GABARs are bicuculline insensitive, RDL thus resembles the majority of insect GABARs, including those expressed on cultured *Drosophila* neurons (Zhang *et al*., 1994).

In some respects, RDL is more similar to $GABA_C$ receptors and the recombinant receptors formed by expression of the vertebrate ρ subunit in their insensitivity to bicuculline and the ability to form functional homo-oligomers. However, it is clear that the agonist site of RDL is dissimilar to that of $GABA_C$ receptors in its preferred pharmacophore. At the sequence level, RDL bears no more closer resemblance to $GABA_C$ receptors than it does to $GABA_A$ receptors, and in fact more closely resembles glycine receptors (ffrench-Constant and Rocheleau, 1992). Thus, while RDL homomers are to be distinguished from $GABA_A$ receptors by their bicuculline insensitivity and the low potency of 3-aminosulfonic acid, they are also to be distinguished from $GABA_C$ receptors by the high efficacy of muscimol and isoguvacine.

5.4.2.4.3.2. The convulsant antagonist site The RDL channel expressed in *Xenopus* oocytes or the *Drosophila* S2 cell line is effectively blocked by 1–10 μM concentrations of PTX, TBPS, EBOB, dieldrin, BIDN, and fipronil (ffrench-Constant *et al*., 1993a, 1993b; Millar *et al*., 1994; Shirai *et al*., 1995; Buckingham *et al*., 1996). For structures of these molecules see **Figures 3–5**. The IC_{50} for PTX block of RDL expressed in *Drosophila* cells was estimated to be 2.5 μM, whereas 10 μM TBPS reduced GABA evoked currents by less than 50%. This higher efficacy of PTX compared to TBPS is also typical of *in situ* insect GABARs, whereas the reverse is true for vertebrate GABARs. Curiously, the RDL homolog from *H. virescens* is insensitive to dieldrin (Wolff and Wingate, 1998). The block of RDL mediated GABA responses by PTX has both competitive and noncompetitive features, in that it reduces the maximal response to GABA and shifts the EC_{50} of the GABA response (Shirai *et al*., 1995). A similar action of PTX was reported for a crustacean GABAR (Smart and Constanti, 1986). As is the case for insect GABARs *in situ*, PTX is a more potent blocker of RDL than TBPS (Buckingham *et al*., 1996), whereas the reverse is true for vertebrate $GABA_A$ receptors.

The convenience of the availability of a robust, functional homomeric GABAR was exploited by Shirai and coworkers (Shirai *et al*., 1995) to determine the key structural elements of the PTX molecule that determine its potency. Using the same approach as that on expressed vertebrate $GABA_A$ receptors (Anthony *et al*., 1993) and *in situ* insect receptors (Anthony *et al*., 1994), the study agreed with earlier ones in that picrotin and PTX acetate were found to be of less efficacy in blocking the GABA response, whereas fluoropicrotoxin was of similar potency to PTX. Thus, the PTX recognition site of RDL resembles that of *in situ* insect GABARs. The potential that RDL offers over *in situ* receptors, namely that the subunit composition is known, could be exploited further in elucidating the mechanisms of action of PTX and related compounds.

These structure–function studies did not uncover any significant difference between vertebrate and insect GABARs at the convulsant site, yet such differences presumably exist, as is inferred from the selectivity of certain insecticides known to act at the convulsant site. Such differences did, however, emerge in a subsequent study by Sattelle and colleagues (Hosie *et al*., 1996), which used a related series of PTX-like compounds, the picrodendrins, to probe the convulsant antagonist site. Picrodendrins

and related tutin analogs are terpenoid toxins present in extracts of a plant of the Euphorbiaceae, *Picrodendron baccatum*. These plants are known as "mata becerro," or calf-killer, in the Dominican Republic where they have been used to kill bed bugs and lice (Ozoe *et al*., 1994). The picrodendrins are structurally similar to PTX, and share its polycyclic lactone picrotoxane skeleton, acting at a similar site in the channel of vertebrate $GABA_A$ receptors (Ozoe *et al*., 1994). The series of terpenoids studied differed mainly in their substituents at the C9 position. In most cases, these substituents were a spiro-γ-butyrolactone ring, providing one of at least two electronegative groups believed to be necessary for picrotoxane activity (Ozoe and Matsumura, 1986). Alteration of these substituents produced differing effects on their potency on RDL when compared to their effectiveness in displacing $[^{35}S]$TBPS from rat membranes (Ozoe *et al*., 1994). First of all, most of the terpenoids were significantly less effective at blocking RDL than at displacing TBPS from rat membranes. More importantly, however, there were considerable differences in their rank order of potency on RDL compared to rat GABARs. Molecules that were most potent against RDL shared an olefin binding that brought the side chains closer to the plane of the spiro-γ-butyrolactone ring than the other compounds. This study succeeded in showing the importance of the position of the electronegative centers in the PTX-like family, which had not emerged from studies restricted to the C4 substituents and the isopropenyl moiety.

The bicyclic dinitrile BIDN, developed in the face of a need for a new, specific ligand for the insect convulsant site, is a potent blocker of recombinant RDL GABA receptors. At 1 μM, BIDN reversibly reduces the amplitude of RDL mediated GABA responses in *Xenopus* oocytes, with only a slight dependence on membrane potential (Hosie *et al*., 1995b). This action was dose dependent, with an IC_{50} that depended upon the concentration of GABA used. When tested against 20 μM GABA the IC_{50} for BIDN action was estimated to be 1.0 μM, whereas when tested against 100 μM GABA it was estimated at 20 μM. This is suggestive of allosteric interactions between the BIDN and GABA ligand binding sites. Like PTX, the action of BIDN displayed both competitive and noncompetitive elements, in that it reduced the maximum GABA induced currents and shifted the dose–response curve to the right, pointing to allosteric actions of BIDN. BIDN also reversibly blocks RDL mediated responses in the S2-RDL and S2-RDL(A302S) cell lines (Buckingham *et al*., 1996). In both the *Xenopus* oocyte and S2 cell line expression systems, it was noticed that GABA responses in the presence of BIDN lacked the desensitization that was so clearly present in control responses (Buckingham *et al*., 1996). One plausible interpretation of this might simply be that, like PTX, BIDN exerts its effects through an enhancement of desensitization, but favoring a different state than PTX. Evidence that BIDN and fipronil both operate by reducing open-state probability, but through different mechanisms, also comes from single channel studies (Grolleau and Sattelle, 2000).

RDL expressed in *Xenopus* oocytes and in a *Drosophila* cell line is sensitive to block by the phenylpyrazole insecticide, fipronil (Millar *et al*., 1994; Hosie *et al*., 1995a). In *Xenopus* oocytes, RDL mediated responses to 50 μM GABA are reduced by up to 80% by 100 μM fipronil. Recovery from fipronil block was very slow, and still incomplete after 10 min washout. This differs from the actions of both PTX and BIDN, which reverse completely and rapidly. Like the block by BIDN (Hosie *et al*., 1995b), fipronil block was voltage independent (Hosie *et al*., 1995a). A further similarity to the actions of both BIDN and PTX is that the action of fipronil consists of both competitive and noncompetitive elements, and is also dependent on the concentration of agonist. Thus, fipronil, BIDN, and PTX share many features (voltage independence, agonist dependence, and mixed mode of action) suggesting that they operate through similar mechanisms. However, it must be noted that whereas PTX and the cyclodienes are competitive inhibitors of $[^3H]$EBOB binding, fipronil is a noncompetitive displacer of $[^3H]$EBOB binding, at least in *M. domestica* (Deng *et al*., 1991, 1993). The possible significance of this in understanding the mechanisms of insecticide resistance is discussed below.

Differences in the action of fipronil and BIDN on RDL were examined in a single channel patch-clamp study (Grolleau and Sattelle, 2000). The ability of RDL to form functional homomers simplifies the interpretation of experiments on the effects of the A302S mutation on single channel properties of the channel. When applied to outside-out patches from S2-RDL cells, GABA (50 μM) evoked inward currents that were completely blocked by 100 μM PTX. As had been reported for outside-out patches of *Xenopus* oocytes expressing RDL, the current–voltage relationship showed slight inward rectification at positive potentials. The conductance of the single channel currents was around 36 pS, but interestingly a 71 pS conductance was observed when the application of GABA was longer than 80 ms. When either 1 μM fipronil or 1 μM BIDN was present in

the external saline, all the GABA gated channels were completely blocked. At lower concentrations, near their respective IC_{50} values, the duration of channel openings was shortened. Interestingly, the blocking action of BIDN resulted in the appearance of a novel channel conductance (17 pS). Examination of the effects of coapplication of these two convulsants (applying 300 nM BIDN with fipronil concentrations ranging from 100 to 1000 nM) revealed an additional BIDN induced dose dependent reduction in the maximum open probability. Thus, while both BIDN and fipronil shorten the duration of wild-type RDLac GABAR channel openings, they appear to do so by acting at distinct sites.

The findings reported to date on the actions of convulsants on RDL agree very closely with their actions on *in situ* insect GABARs. The agonist dependence and mixed competitive/noncompetitive action are consistent with a model of PTX action in which the PTX molecule binds preferentially to an agonist-bound conformational state of the receptor and hence increases the probability of a transition into a desensitized state. Such a conclusion was advanced to explain similar properties of PTX action at the crayfish neuromuscular junctional GABARs (Smart and Constanti, 1986) and the finding that the rate of development of a steady-state blockade of GABARs on rat sympathetic neurons was enhanced when GABA is applied in brief, rapidly repeated doses (Newland and Cull-Candy, 1992).

RDL has also been used to predict cross-resistance to insecticides acting at the convulsant site. Dieldrin resistant RDL mutant GABARs are not only comparatively insensitive to PTX, but are also insensitive to BIDN (Hosie *et al.*, 1995b). Similar results were obtained for fipronil (Hosie *et al.*, 1995a) although other workers reported different results (Wolff and Wingate, 1998). Furthermore, a novel tricyclic dinitrile, KN244, blocks RDL and the sensitivity of dieldrin resistant RDL to it is reduced 100-fold (Matsuda *et al.*, 1999).

*5.4.2.4.3.3. **Allosteric modulators*** Responses mediated by RDL are sensitive to potentiation by benzodiazepines, but their benzodiazepine pharmacology differs from *in situ* insect receptors. Insect GABA responses are potentiated by Ro 5-4864 and flunitrazepam. Responses to GABA mediated by RDL expressed in *Xenopus* oocytes (Hosie and Sattelle, 1996b) were potentiated by micromolar concentrations of Ro 5-4864. In contrast, the same receptor expressed in the *Drosophila* S2 cell line appeared to be insensitive to Ro 5-4864 (Millar *et al.*, 1994), although enhancement was obtained when the concentration of the benzodiazepine was increased to 100 μM (Buckingham *et al.*, 1996b). This illustrates that caution must be exercised in interpreting negative data until a wide range of ligands is tested. However, flunitrazepam, which is active at GABARs on cockroach motor neuron, D_f, at micromolar concentrations, was found to be ineffective on RDL in either expression system even at concentrations of 100 μM (Millar *et al.*, 1994; Hosie and Sattelle, 1996b). This represents a departure from most *in situ* insect receptors studied to date. Significantly, the identified motor neuron D_f of the cockroach stains positively to the RDL antibody (Sattelle, personal communication), suggesting that in this cell at least, RDL may coassemble with another subunit. Flunitrazepam is also reported to have no effect on a GABAR cloned from *H. virescens* (Wolff and Wingate, 1998). Nonetheless, the comparatively low sensitivity of RDL to benzodiazepines, coupled with its sensitivity to the "peripheral" benzodiazepine, Ro 5-4864, are both characteristic of insect receptors compared to that of vertebrates.

That RDL should differ from *in situ* receptors principally at the benzodiazepine site is not surprising, given the wide variation in benzodiazepine pharmacology of GABARs generally, and may indicate that RDL coassembles with another subunit subtype *in situ*. Since only two other GABARs have been cloned from *Drosophila* to date, these are the obvious candidates for the other subunit. However, it is unlikely that LCCH3 is the additional subunit, since, as described above, receptors formed by coexpression of RDL with LCCH3 are quite unlike insect receptors. In any case, the lack of overlap of expression of these two subunits at any stage of development makes it highly unlikely that they coassemble *in vivo*. The question of whether RDL forms a homomer *in situ* is discussed in a separate section below. Unfortunately, coexpression of RDL with GRD has yet to be described. While expression studies on the agonist pharmacology of three of the four RDL splice variants has been described in some detail (Chen *et al.*, 1994; Hosie and Sattelle, 1996a), benzodiazepine pharmacology of these variants, or combinations of them, has not yet been assayed.

Like *in situ* insect receptors, RDL is potentiated by barbiturates. In both the *Xenopus* oocyte and the *Drosophila* S2 cell line expression systems, RDL mediated GABA responses were enhanced by either sodium phenobarbitone or sodium pentobarbitone by up to 50% of control values (Hosie and Sattelle, 1996b; Buckingham *et al.*, 1996). Similar results were reported for the RDLbd splice variant, whose responses were enhanced up to fivefold (Belelli *et al.*,

1996a). Similarly, the RDL equivalent cloned from *H. virescens* is also subject to barbiturate (phenobarbital) enhancement (Wolff and Wingate, 1998). In contrast to vertebrate GABARs, which are also sensitive to barbiturates, elevation of the barbiturate to high (1 mM) concentrations did not evoke *Drosophila* RDL mediated currents in the absence of GABA (Belelli *et al*., 1996a; Buckingham *et al*., 1996). It is therefore likely that the two components of barbiturate action on vertebrate receptors – the enhancement of the GABA response and the direct opening of the channel in the absence of GABA – are mediated by two separate sites, of which only one may be present on insect GABARs.

RDL is comparatively insensitive to steroids. The steroid, 5α-pregnan-3α-ol-20-one, enhances human $\alpha_3\beta_1\gamma_{2L}$ receptors, but at high concentrations had only a minimal effect on RDLbd (Belelli *et al*., 1996) and RDLac (Millar *et al*., 1994; Hosie and Sattelle, 1996b). Insect GABARs *in situ* are also highly insensitive to steroids (Rauh *et al*., 1990).

The anticonvulsant, loreclezole, is a potentiator of vertebrate recombinant GABARs containing the β_2 or β_3 subunit (Wafford *et al*., 1995), but not of those containing a β_1 subunit (Wingrove *et al*., 1994). This is attributed to the presence of a serine in the β_2 and β_3 subunits, which is an asparagine at the equivalent position in the β_1. Curiously, although a mutation of this serine to a methionine abolishes loreclezole sensitivity (Stevenson *et al*., 1995), RDL (which has methionine at this position) is sensitive to loreclezole (Belelli *et al*., 1995; Hosie and Sattelle, 1996b).

RDL is also sensitive to a number of other allosteric modulators. Isoflurane enhances GABA responses mediated by expressed RDL and blocks at higher concentrations. This block is not seen for the cyclodiene resistant A302S mutant, suggesting that the block is due to an interaction at the PTX site (Edwards and Lees, 1997).

These data amply illustrate the usefulness of the cloned RDL receptor in advancing our understanding of insect GABARs. More than this, however, RDL, because of its ability to form functional homomers, has also been of use in structure/function studies on allosteric modulator sites of vertebrate GABARs. For instance, RDL is insensitive to the anesthetic etomidate, as are vertebrate β_1 subunits. Vertebrate β_2 and β_3 subunits, however, do confer sensitivity to etomidate and this is attributable to the presence of an asparagine residue at equivalent positions in a transmembrane-spanning domain, which is a methionine at the equivalent position in RDL. Mutating M314 to an asparagine in RDL rendered the expressed receptors sensitive to enhancement by etomidate (McGurk *et al*., 1998). As in vertebrate recombinant receptors, this sensitivity is stereospecific, whereas the native sensitivity to pregnane steroids or pentobarbitone remained unchanged. Conversely, the N289M mutation introduced into vertebrate β_2 abolished the etomidate sensitivity. Such complementarity of effects of mutation encourages confidence in interpreting experiments using an invertebrate receptor as a model of vertebrate receptors, especially in view of the comparative simplicity of interpreting data obtained using homomers.

5.4.2.4.3.4. Other (RDL) ligands RDL, like GABARs of the motor neuron, D_f, of the cockroach (Bai, 1994), is insensitive to zinc (Hosie and Sattelle, 1996b), which blocks many vertebrate $GABA_A$ receptors (Hosie *et al*., 2003), as well as ρ receptors.

5.4.2.4.4. Conclusions There can be little doubt that the availability of RDL has accelerated the pace of research into the molecular pharmacology of insect GABARs. The chief advantage that it confers, in addition to the convenience of performing experiments on oocytes, is that hitherto studies aimed at uncovering the mechanisms of drug–receptor interaction for insect GABARs have been hindered by the fact that in no case is the subunit composition of any *in situ* GABAR known. It is of great significance that a number of different laboratories have confirmed independently that whatever the expression system chosen (*Xenopus* oocytes, *Drosophila* S2 cells, *Spodoptera* Sf9 cells), the pharmacology of the expressed RDL receptor does not differ significantly. Indeed one paper (Buckingham *et al*., 1996) examined this issue directly. This encourages confidence that RDL is not coexpressing with GABAR subunits native to the respective expression systems, and that we can be reasonably certain that the subunit composition of the expressed RDL receptor is a homomeric pentamer. To appreciate the significance of such an advantage, we have only to look at the advances in understanding of nicotinic receptors that emerged from research using another homomer forming receptor, the vertebrate nicotinic α_7 receptor.

Since RDL homomers so closely mimic *in situ* GABARs, and since RDL antibody staining corresponds closely to GABA immunoreactivity, it is likely that RDL contributes to most of the GABARs in the insect brain. In view of the conclusion drawn above that there is pharmacological diversity of subtypes of GABARs in insects, the question of the source of this diversity remains to be addressed. The occurrence of alternative splicing and RNA

editing may add to functional diversity of the small *Drosophila* GABAR gene family. Evidence for this possibility is discussed in the following section.

5.4.2.4.5. Alternative splicing in GABA receptor subunits RDL is expressed in the form of four splice variants, arising from alternative splicing of two of its nine exons (exons 3 and 6). These four distinct polypeptides show characteristic structural features of a GABAR subunit. The regions in which the splice variants differ align closely with regions known to be determinants of agonist potency in vertebrate ionotropic receptor subunits. This is highly unusual. Although there are many examples of alternatively spliced GABAR subunit genes in vertebrates, the splicing usually occurs in their large intracellular loops. All four of these splice variants are expressed in embryonic *Drosophila* (ffrench-Constant and Rocheleau, 1992), yet their functional roles remain to be determined.

Since the pharmacological diversity observed among vertebrate $GABA_A$ receptors arises at least in part from the assorted assembly from different subunit isoforms, the alternate splicing of the *rdl* gene may serve a physiological role by increasing receptor diversity. Since RDL appears to be a component of the majority of insect GABARs, such a splicing mechanism may represent another route to subunit diversity in a small GABAR gene family. Evidence that alternative splicing confers pharmacological diversity comes from expression studies that have described pharmacological differences between these variants at the agonist site. For example, the three splice variants tested to date in functional expression studies (RDLac, RDLad, RDLbd) all differ in their EC_{50} values for GABA (Hosie and Sattelle, 1996a). The region in which these variants differ include loop F of the GABA binding site.

5.4.2.4.6. Does RDL form a homomer *in situ*? Despite our limited knowledge of the pharmacology of native GABARs of *Drosophila*, it is clear that RDL homomers mimic closely the pharmacology of insect GABARs. The general features that distinguish most insect GABARs from those of vertebrates – insensitivity to bicuculline, comparative insensitivity to benzodiazepines, sensitivity to the peripheral benzodiazepine Ro 5-4864, insensitivity to TBPS, and sensitivity to isoguvacine – are all seen in RDL homomers. The only challenge to this, the insensitivity of RDL to flunitrazepam, is perhaps not particularly serious in view of the diversity of benzodiazepine pharmacology amongst $GABA_A$ receptors studied to date and the acute dependence of benzodiazepine pharmacology upon subunit composition. Where this difference in benzodiazepine pharmacology gains significance, though, lies in the observation that a *Drosophila* anti-RDL antibody stains motor neuron D_f of the cockroach (Sattelle, personal observation), which is known to possess GABARs sensitive to micromolar concentrations of flunitrazepam (Sattelle *et al*., 1988). Since RDL, which is flunitrazepam insensitive, is expressed on D_f, which is flunitrazepam sensitive, this difference hints at the existence of another subunit subtype in these cells.

Single channel recordings also provide reason to suspect that RDL may not always exist as a homomer *in situ*. Single, GABA gated channels recorded from *Xenopus* oocytes injected with *rdl* cRNA were inwardly rectifying, with inward and outward currents of around 21 pS and 12 pS, respectively (Zhang *et al*., 1994). GABA gated single channels recorded from *Drosophila* larval neurons in culture, although also inwardly rectifying, had inward and outward conductances of around 28 and 29 pS, respectively (Zhang *et al*., 1994), a value significantly different from expressed RDL homomers. Mean open times of RDL homomers in *Xenopus* oocytes were significantly shorter than single GABA gated channels in cultured *Drosophila* neurons: around 62 ms compared to 118 ms, respectively. A simple explanation for these findings would be that RDL coexpresses with another subunit *in situ*.

However, single channels recorded from a *Drosophila* S2 cell line stably expressing RDL were estimated to be 36 pS (Grolleau and Sattelle, 2000), a value also significantly different from values for RDL recorded in oocytes. Both these studies used the same concentration of GABA (50 μM) and both used brief applications of GABA to outside-out patches. So it is likely that this difference is due to the different expression environments or perhaps the different ionic compositions of the recording media. Given that no other differences in pharmacology have been detected to date between the two expression systems, and that both studies identified a slight inward rectification, the latter is the more likely explanation. It is interesting to note that Grolleau and Sattelle (2000) reported the emergence of a larger conductance when the duration of the GABA pulse was prolonged to over 80 ms, suggesting that the conductance properties of this channel may be more complex than hitherto suspected.

Does RDL coexpress with the other two insect GABAR subunits known to date, LCCH3 or GRD? LCCH3 (Henderson *et al*., 1993) closely resembles vertebrate $GABA_A$ receptor β subunits. Neither LCCH3 nor GRD form functional homo-oligomeric receptors in *Xenopus* oocytes (Harvey

et al., 1994; Zhang *et al.*, 1994). When coexpressed with RDL in baculovirus transfected *Spodoptera frugiperda* Sf21 cells, however, LCCH3 forms a receptor that exhibits a biphasic response (Zhang *et al.*, 1994), which only becomes clear during prolonged applications of GABA (>1 s). The first component was a rapidly activating, rapidly desensitizing current with kinetics indistinguishable from those of RDL expressed alone. The second component, however, was of much slower kinetics of activation and desensitization, and was attributed to the RDL/LCCH3 combination. The coapplication of 500 μM PTX completely abolished the fast component and blocked about half of the slow current. In contrast, bicuculline (100 μM) completely abolished the slow component leaving the fast component unaffected. One simple explanation of these findings is that the fast component is attributable to RDL homomers that, in accord with other reports, is PTX sensitive and bicuculline insensitive, and that the slow response is mediated by RDL/LCCH3 multimers. This provides evidence that LCCH3 can indeed form a receptor when coexpressed with RDL, but the resulting receptor differs significantly from the pharmacology of all known insect GABARs with respect to picrotoxinin. Their sensitivity to bicuculline further distinguishes them from GABARs of cultured *Drosophila* neurons (Zhang *et al.*, 1994). Furthermore, expression of LCCH3 and RDL do not overlap in the adult–LCCH3 is expressed in cell bodies (Aronstein *et al.*, 1996) whereas RDL expression is restricted to neuropil and is not observed in *Drosophila* cell bodies (Aronstein *et al.*, 1995), although it is observed in cell bodies in other species (Harrison *et al.*, 1996). We therefore conclude that it is unlikely that RDL coexpresses with LCCH3 *in vivo*. It would be most interesting to establish whether perhaps LCCH3 contributes to the formation of bicuculline sensitive GABARs of the kind that are known to exist in *M. sexta* (Waldrop *et al.*, 1987).

One intriguing recent finding suggests that the additional subunit, from which we have excluded LCCH3 as a candidate, may not even be a GABAR subunit. Immunoprecipitation studies using antibodies to a *D. melanogaster* glutamate gated chloride channel (DmGluCl) showed that: (1) DmGluCl alpha antibodies precipitated all of the ivermectin and nodulisporic acid receptors solubilized by detergent from *Drosophila* head membranes; and (2) they also immunoprecipitated all solubilized nodulisporic receptors, but only approximately 70% of the ivermectin receptors (Ludmerer *et al.*, 2002). These data suggest that both DmGluCl α and RDL are components of nodulisporic acid and ivermectin receptors.

Finally, it is of interest to note the recent finding by O'Dowd and colleagues that RDL is involved at GABAergic synapses formed in cultures of embryonic *Drosophila* neurons (Lee *et al.*, 2003). Furthermore, the authors conclude that other subunit(s) are also involved.

5.4.2.5. Intracellular Modulation of GABARs

Ionotropic receptors are potentially susceptible to modulation by intracellular factors. This may alter their density, kinetics, or pharmacology, and may be an important component in long-term changes in synaptic function, such as may be involved in learning. One type of GABAR present on cockroach (*P. americana*) DUM neurons is regulated by changes in intracellular calcium through a calcium dependent protein kinase pathway (Alix *et al.*, 2002). Similarly, maintenance of GABA responses in isolated neurons from *P. americana* abdominal ganglia requires phosphorylation as well as, possibly, a nucleotide recognition site unrelated to PKA-dependent phosphorylation (Watson and Salgado, 2001). However, although RDL contains possible sites for intracellular phosphorylation (ffrench-Constant *et al.*, 1991), no rundown of RDL mediated responses is seen in *Drosophila* S2 cells in whole-cell patch clamp mode, even when no ATP is included in the pipette (Buckingham, personal observation). This does not, however, exclude the possibility that RDL is subject to modulation by intracellular signaling pathways. The latter is likely to provide a fertile area of study in the future, especially in view of the observations that suggest that RDL may be closely implicated in learning.

5.4.2.6. GABARs as Targets for Insecticides

Insect GABARs are the major targets for several chemically distinct classes of insecticidally active molecules: trioxabicyclooctanes, dithianes, silatranes, lindane, toxaphene, bi- and tricyclic dinitriles, chlorinated cyclodienes, and picrotoxinin (Deng *et al.*, 1991; Rauh *et al.*, 1997). These sites overlap, since [^{3}H]EBOB is displaced by all these compounds. The importance of the convulsant site for the insecticidal action is illustrated by the close linear correlation between the effectiveness of their displacing [^{3}H]EBOB binding from house fly head membranes and their LD_{50} (Deng *et al.*, 1991).

5.4.2.6.1. Picrotoxin Picrotoxin was used as an early insecticide in the preservation of lard (Bentley and Trimen, 1875). Picrotoxin contains picrotin and picrotoxinin. The radiolabeled form of picrotoxinin ([^{3}H]DHPTX) was used as an early probe of insect GABARs, but was later superseded by [^{35}S]TBPs.

5.4.2.6.2. Polychlorocyclohexanes Chemicals of this group, notably lindane, benzene hexachloride, and α-endosulfan, were used intensively as insecticides in the postwar years, until recent environmental concerns led to their disuse, with the exception of α-endosulfan. Binding (Lawrence and Casida, 1984) and electrophysiological (Wafford *et al.*, 1989) studies confirmed that they act at ionotropic GABARs.

5.4.2.6.3. Bicyclophosphorus esters and bicycloorthobenzoates The radioligand probe [^{35}S]TBPS overtook [^{3}H]DHPTX as the most useful probe of vertebrate GABA gated chloride channels. However, insect GABARs are comparatively insensitive to TBPS (Lummis and Sattelle, 1986) compared to vertebrate $GABA_A$ receptors, and the bicyclophosphorus esters have comparatively low insecticidal activity (Casida *et al.*, 1988). The next development arose from the discovery that the addition of a substitute benzene ring to the bicyclic ring greatly increased insecticidal potency (Palmer and Casida, 1985), as well as affinity for the convulsant site (Lummis and Sattelle, 1986). Selection for the optimal substituents gave rise to the bicycloorthobenzoates, of which the most frequently used are EBOB (1-(4′-ethyphenyl)-4-[2,3]propyl-2,6,7-trioxabicyclo [2.2.2]octane) (**Figure 3**) and TBOB. EBOB has proven particularly useful in characterizing the convulsant site of houseflies (Cole and Casida, 1992; Deng *et al.*, 1993) and *Drosophila* (Cole *et al.*, 1995).

5.4.2.6.4. Phenylpyrazoles The phenylpyrazole insecticide fipronil (**Figure 4**) is an effective pest control agent even at low doses (Tingle *et al.*, 2003). It has many characteristics that make it suitable: it degrades slowly with a half-life of 36 h to 7 months and it leaches out slowly into groundwater. Unfortunately, its toxicity to certain vertebrates may limit the use of fipronil insecticides.

Fipronil competes for the [^{3}H]EBOB binding site, along with α-endosulfan and lindane (Ratra and Casida, 2001), indicating that it acts at the convulsant site. RDL from *Drosophila* and *Heliothis* are both blocked micromolar concentrations of fipronil (Hosie *et al.*, 1995a; Wolff and Wingate, 1998), and fipronil reduces GABA gated currents in RDL by shortening the duration of openings (Grolleau and Sattelle, 2000). In addition to GABA gated chloride channels, fipronil also blocks glutamate gated chloride channels on DUM neurons of cockroach (Raymond *et al.*, 2000), but not histamine gated chloride channels of *Drosophila* eye (Zheng *et al.*, 2002). GLC-3, a homomer-forming recombinant glutamate gated chloride channel from *C. elegans*, is blocked by fipronil.

That fipronil and dieldrin both act at similar sites on insect GABARs allowed the prediction that cross-resistance between these insecticides will occur (Hosie *et al.*, 1995a). This was confirmed in a recent study that showed cross-resistance to dieldrin in a fipronil resistant mosquito line, and cross-resistance to fipronil in a dieldrin resistant mosquito line (Kolaczinski and Curtis, 2004).

5.4.2.6.5. Avermectins Avermectins (**Figure 7**) have been used as insecticides (e.g., abamectin) as well as endectocides (e.g., ivermectin) (review: Bloomquist, 1996 and (see **Chapter 5.2**). In addition to their actions on inhibitory glutamate receptors, avermectins also displace binding of EBOB to *Drosophila* membranes at 20 nM. This is also true of the dieldrin resistant mutant form of RDL (Cole *et al.*, 1995). Ivermectin binds to neuronal membranes of *D. melanogaster* and the locust, with nanomolar K_ds (Rohrer *et al.*, 1995). Although glutamate gated chloride channels are probably the principal site of action of avermectins, their insecticidal actions may also be due, at least in part, to actions on GABARs (Bloomquist, 1996). Their insecticidal actions can have a deleterious ecological effect where they are used as endectocides on cattle, as the presence of avermectins excreted in the dung is detrimental to dung dwelling insects (McCracken, 1993; Strong, 1993), slowing normal biodegradation.

5.4.2.7. Mechanisms of Insecticide Resistance

Resistance to insecticides is common in field populations of many insect species (Georghiou, 1986). Early binding studies provided evidence that resistance to cyclodienes is due largely to changes in the target site. The dissociation constant and saturation level of a cyclodiene resistant strain (Lpp) of the cockroach, *B. germanica*, differed from those of the wild-type (Matsumura *et al.*, 1987). These differences corresponded to an approximately tenfold reduction in affinity. A number of studies on geographically separate populations of *D. melanogaster* provided clear evidence of cross-resistance between cyclodiene insecticides and PTX (Kadous *et al.*, 1983; Matsumura and Ghiasuddin, 1983; Wafford *et al.*, 1989; Deng *et al.*, 1991; ffrench-Constant and Roush, 1991), again implicating changes in the convulsant site as a mechanism of resistance to the action of insecticides.

In the *rdl* (resistant to dieldrin) *Drosophila* strain, insecticide resistance arises from the substitution of a single amino acid (A302S), which contributes to

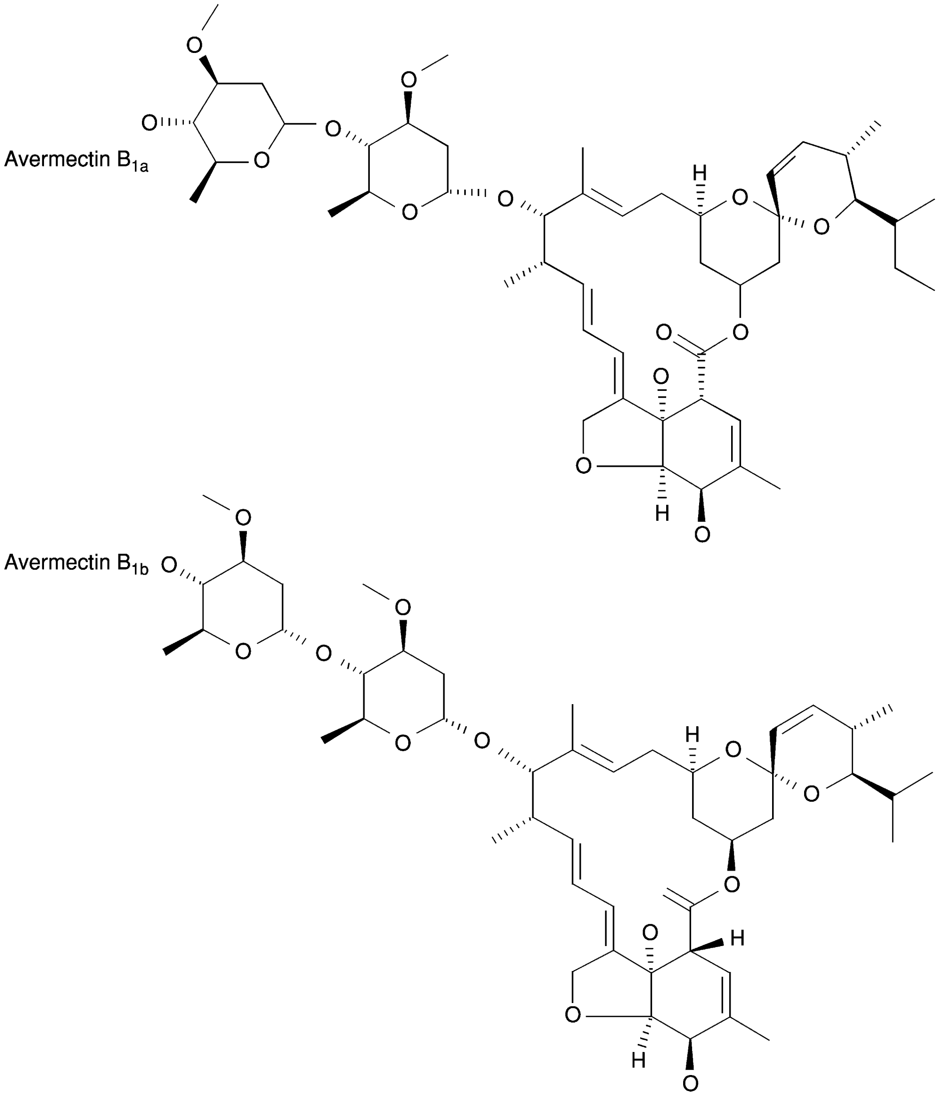

Figure 7 The molecular structures of avermectin B_{1a} and avermectin B_{1b}.

the M2 pore forming region of the GABAR channel. It is close to a site that determines charge selectivity in nAChRs (Imoto *et al.*, 1988; Leonard *et al.*, 1988). A similar mutation (A285S) confers dieldrin insensitivity to a cloned *H. virescens* RDL equivalent (Wolff and Wingate, 1998). Similarly, cyclodiene resistance in the aphid, *Nasonovia ribisnigri*, a main pest of salad crops, is also due to an A302S mutation (Rufingier *et al.*, 1999). In the peach aphid, *M. persicae*, cyclodiene resistance is due to a mutation of A302, but in this case three mutations 5 A302Gly, Ser (TCG), and Ser (AGT), can generate resistance (Anthony *et al.*, 1998). Study of wild *T. castaneum* suggests multiple origins of cyclodiene resistance (Andreev *et al.*, 1999), whereas the mutation probably has a single origin in the case of *D. melanogaster* (ffrench-Constant *et al.*, 2000). Indeed, the central importance of the RDL A302S mutation is reflected in the observation that a mutation of this amino acid is implicated in cyclodiene resistance in at least 60 strains of *D. melanogaster* and *D. simulans* collected worldwide (ffrench-Constant *et al.*, 1993a).

The A302S mutant receptor has a greatly reduced sensitivity to PTX. When expressed in *Xenopus* oocytes, wild-type RDL supports GABA responses that are completely blocked by 10 µM PTX, whereas RDL-A302S mediated responses are only about 50% blocked by the same concentration (ffrench-Constant *et al.*, 1993a, 1993b). The same study showed that sensitivity to dieldrin is also reduced. Dieldrin at 10 µM reduced the amplitude of wild-type responses by some 75%, whereas the mutant was almost completely insensitive to the

concentrations tested. Similar results are obtained regardless of the expression system. GABA responses mediated by RDL stably expressed in a *Drosophila* cell line (S2) were blocked by PTX with an IC_{50} of approximately 2 μM, whereas in the case of an S2 cell line stably expressing the A302S mutant, 100 μM PTX produced a maximum block of only about 30% (Buckingham *et al*., 1996). The A302S mutation is not known to have any effect on agonist pharmacology.

The A302S substitution confers resistance to a variety of naturally occurring (e.g., picrotoxinin, picrodendrin-O) and man-made (e.g., fipronil) insecticides, which act allosterically as noncompetitive antagonists of insect GABARs. The A302S substitution also renders RDL homomers and native receptors resistant to the antagonists TBPS, lindane, and BIDN (Belelli *et al*., 1995; Buckingham *et al*., 1996; Hosie *et al*., 1995b). However, these compounds interact noncompetitively in radioligand binding studies, suggesting that they have distinct, if overlapping, binding sites. The A285S mutant RDL of *H. virescens* is also resistant to fipronil and picrotoxinin to similar degrees as the *Drosophila* RDL mutant (Wolff and Wingate, 1998).

Studies on vertebrate $GABA_A$ receptors have suggested that PTX blocks the channel via an allosteric mechanism in which it binds preferentially to activated channels and stabilizes them in the agonist-bound, closed conformation (Smart and Constanti, 1986; Newland and Cull-Candy, 1992). It appears that one effect of the RDL A302S mutation is to stabilize the open conformation and reduce the rate of desensitization (Zhang *et al*., 1994). In addition, the A302S mutation lowers the binding affinity for PTX (Cole *et al*., 1995; Lee *et al*., 1994). Since the sites for all the convulsant antagonists overlap, we can assume that similar mechanisms apply to other cyclodienes. In this context, it is interesting to observe that although the substitution of a serine for an alanine does not introduce any change in net charge, the added hydroxyl group is more bulky and may restrict access of the PTX molecule by steric interference (ffrench-Constant *et al*., 1993a, 1993b). It has also been observed (Hosie *et al*., 1995a) that the A302S mutation both alters the rate of desensitization and reduces the potency of PTX as well as that of fipronil. PTX and dieldrin both displace EBOB binding competitively in *M. domestica*, whereas fipronil's displacement of EBOB is noncompetitive. It has been suggested (Zhang *et al*., 1994) that the A302S mutation must either alter both the fipronil and PTX binding sites, or perhaps instead, alters the allosteric linking mechanism by which convulsants reduce GABA responses, or both.

5.4.2.8. Molecular Basis of Selectivity of Insecticides for Insect GABARs

Many currently used insecticides have been developed for their selective toxicity to insects compared to vertebrates. Much of this is attributable to differences between the sites of action within the channel pore. For example, fipronil is more toxic to insects than to vertebrates because it has a higher affinity for insect GABARs (Hainzl *et al*., 1998). However, binding of EBOB, fipronil, lindane, and endosulfan to housefly head membranes is comparable to the binding to human recombinant β_3 GABARs, attributable to sequence similarities at key points on their receptors. Studies of recombinant human $GABA_A$Rs show subunit dependency of insecticide affinity (Ratra and Casida, 2001). Similarly, the potency of lindane, fipronil, EBOB, and α-endosulfan on human recombinant $GABA_A$ receptors is dependent on the specific type of α or γ subunit present (Ratra *et al*., 2001). A detailed study on the actions of picrodendrin and tutin antagonists on RDL expressed in oocytes (Hosie *et al*., 1996) suggested that insect and vertebrate GABARs differ in their ideal convulsant site pharmacophore. The same conclusion is confirmed by similar studies using systematic variations of a class of molecules. For instance, acyclic esters compete with EBOB and changes to these molecules result in increases in potency against housefly head membranes, whereas their potency against rat GABARs is unchanged or reduced (Hamano *et al*., 2000). A study using a series of 28 picrotoxane terpenoids concluded that rat GABARs require a spiro-γ as butyrolactone moiety at the 13 position and certain substituents at the 4-position, whereas these are not critical for interactions with *Musca* receptors. The electronegativity of the 16-carbon atom and the presence or absence of the 4- and 8-hydroxyl groups are important determinants of nor-diterpenes for *Musca* GABARs, again suggestive of differences in rat binding sites compared to *M. domestica* (Ozoe *et al*., 1998).

Differences in receptor sites are not the only mechanisms of insecticide selectivity. Fipronil is an interesting case, in that metabolic detoxification contributes positively to insect selectivity. Although selective toxicity of fipronil for insects is at least partly due to its higher affinity for the convulsant site, it is also due to differences in the rate at which it is broken down to its more active sulfone metabolite (Hainzl *et al*., 1998).

5.4.2.9. Single Channel Properties of Insect GABARs

It has proved difficult to obtain patch-clamp recordings of single GABA gated chloride channels of

insects, and this has been attributed to a heterogenous distribution of GABARs over the cell membrane (Pichon and Beadle, 1988). Noise analysis of cultured embryonic cockroach (*P. americana*) brain neurons gave an estimate of single channel conductance of 18.6 pS and mean open time of 11.8 ms (Shimahara *et al.*, 1987). Single channel recordings of GABA gated currents in cultured adult *P. americana* neurons indicated two open conductance states, with single channel conductances of around 17 and 11 pS and two mean open times of around 0.28 and 1.43 ms, as well as three closed states with mean durations of 0.25, 2.22, and 43.7 ms (Malecot and Sattelle, 1990). An RDL splice variant, RDL_{ac}, expressed in a *Drosophila* cell line has single channel conductance of 36 pS. Mean open time distribution was best fitted to two time constants, suggesting that there are two open states (Grolleau and Sattelle, 2000).

5.4.2.10. Distribution

GABARs are present throughout the insect brain (Sattelle, 1990), but this distribution is not uniform. GABAR localization at the tissue level reflects not only behavioral roles, such as in learning and receptive field sharpening, but possibly also its role in development. Fine details of distribution also provide clues to their possible functional roles. For example, GABARs are distributed over the terminals of primary auditory afferents in certain crickets, and are located near output synapses, suggesting that they play a role in presynaptic inhibition (Hardt and Watson, 1999).

A number of studies have indicated particularly dense GABAR expression in brain structures associated with learning, in accord with the observations described below, which point to a central role of GABAergic inhibitory pathways in the consolidation of memory. It has been mentioned above that antibodies to RDL, a *D. melanogaster* GABAR subunit, shows strong immunoreactivity in cockroach, *P. americana* (Harrison *et al.*, 1996) and cricket *A. domesticus* (Strambi *et al.*, 1998) mushroom bodies. Similar results were obtained in the cricket *Gryllus bimaculatus* (Schurmann *et al.*, 2000), and the fly *C. erythrocephala* (Brotz *et al.*, 1997). The three types of GABA immunoreactive neurons in the mushroom bodies of the cockroach (Yamazaki *et al.*, 1998) are described below. We can therefore conclude that high levels of expression of RDL-like GABARs is a common feature of insect mushroom bodies.

In addition to high level GABAR expression, there is evidence that GABAergic intrinsic neurons in the mushroom bodies form distinct compartments. In the fly *C. erythrocephala*, a RDL antibody stains concentrically around an unstained core in the pedunculus and α and β lobes of the mushroom body, whereas the γ-lobes showed a compartmentalized RDL staining. That only some of the neurons, presumably Kenyon cells, should be stained suggests that only some Kenyon cells have GABARs and are therefore non homogeneous (Brotz *et al.*, 1997). Similar compartmentalization is seen in the arborizations of GABAergic input neurons in *G. bimaculatus* and *D. melanogaster* (Schurmann, 2000). The functional significance of this compartmentalization is as yet unknown, but may be related to the finding that each Kenyon cell specifically connects corresponding layers of the calyces and lobes (Grunewald, 1999).

In addition to intrinsic neurons of the mushroom body, certain input and output neurons are also GABAergic (Nishino and Mizunami, 1998), although most of them are cholinergic, at least in *D. melanogaster* and *G. bimaculatus* (Schurmann, 2000). The calycal giants (the input neurons to the Kenyon cells of the mushroom bodies) are GABA immunoreactive (Nishino and Mizunami, 1998). In *D. melanogaster* and *G. bimaculatus*, GABA immunoreactive presynaptic fibers of extrinsic neurons intermingle with nonimmunoreactive fibers in the mushroom bodies (Schurmann, 2000).

There may be close association between GABA expression and expression of nitric oxide (NO) in the insect nervous system. The synthesis of NO is under the control of NADPH-diaphorase. In the locust, almost all GABAergic neurons in the brain were also found to be NADPH-diaphorase positive (Seidel and Bicker, 1997), suggesting that GABA and NO could be cotransmitters.

Distribution of GABAergic neurons is also likely to be determined by developmental constraints. GABA immunoreactive neurons are linearly determined in *M. sexta* (Witten and Truman, 1991). In this species, and probably in eight other insect orders, GABA immunoreactive neurons are restricted to six lineages (Witten and Truman, 1998). Similarly, the approximately 360 GABAergic neurons in the larval midbrain of *T. molitor* form ten distinct clusters. The number of GABAergic somata, but not the number of clusters, increases during development (Wegerhoff, 1999). As NADPH-diaphorase activity in grasshoppers is detected as early as embryonic stage 50%, and since all NADPH-diaphorase positive local interneurons of adult antennal lobe also express GABA immunoreactivity, this is the earliest reported appearance of GABA immunoreactivity in the embryonic antennal lobe (Seidel and Bicker, 2002).

Antibodies to GABA and GABAR associated proteins also stain other parts of the insect CNS that perform roles in sensory and motor processing. In the locust *S. gregaria*, GABA immunoreactivity and GAD immunoreactivity are both observed in about 100 bilateral pairs of tangential neurons that connect the lateral accessory lobes to distinct layers of the central body in the central complex, a structure that plays a role in motor control and visual orientation (Homberg *et al.*, 1999). The brain of the moth *M. sexta* contains some 20 000 GABAergic neurons, most of which are optic lobe neurons (Homberg *et al.*, 1987), although there is also abundant staining in the mushroom bodies (Homberg *et al.*, 1987) and the antennal lobes (Hoskins *et al.*, 1986). In locusts GABA has also been shown to be colocalized with locustatachykinin immunoreactive local interneurons, a distinct subset of antennal lobe neurons (Ignell, 2001). In *D. melanogaster*, the RDL antibody stains the calyces of mushroom bodies, glomeruli of antennal lobes, lower central body and corpora cardiaca, as well as medulla and lobula regions of the optic lobe: regions associated with olfactory, visual, and mechanosensory processing (Harrison *et al.*, 1996). In the same species, immunoreactivity to GABA is reported in the larval antennal lobe and the tritocerebral-subesophageal ganglion. Whereas choline acetyltransferase (ChAT) is expressed only in subsets of olfactory and gustatory afferents, GABA is expressed in most, if not all, local interneurons (Python and Stocker, 2002). Immunostaining for an insect GABA transporter in *M. sexta* closely matches that for GABA, with staining in parts of the optic and antennal lobes, mushroom body, lateral protocerebrum, and central complex (Umesh and Gill, 2002).

GABARs are also present on identified neurons of certain insects, notably the fast coxal depressor motor neuron (D_f) (Sattelle *et al.*, 1988), the GI2 escape neuron of the cockroach *P. americana* (Hue, 1991; Buckingham *et al.*, 1994), and fg1 (a neuron in the frontal ganglion of *M. sexta*), as well as unidentified dorsal unpaired median neurons of *P. americana* (Sattelle *et al.*, 2003).

5.4.2.11. GABARs and Behavior

By 1985 evidence had already accumulated pointing to the roles of GABARs in fast inhibitory responses on giant interneurons that process sensory input in the cockroach *P. americana*, and in auditory processing in the cricket. Recent work has expanded considerably on these findings, as well as added to the list of roles played by GABARs in generating insect behavior.

Demonstrations of the involvement of GABARs in behavior usually consist of descriptions of GABARs or GABAergic neurons in circuits or structures known to be involved in specific behaviors, or reports of effects of GABAergic drugs exerting specific actions on discrete aspects of behavior. Two areas that have received considerable attention over the past 10 years have been insect learning, where GABARs have been shown to be particularly abundant in the antennal lobe and mushroom bodies, and the tuning of sensory encoding, in which GABAergic inhibitory pathways have been shown to sharpen receptive fields or enhance sensory discrimination.

5.4.2.11.1. Insect learning There have been a number of convincing demonstrations that structures in the insect brain known to be involved in the acquisition, consolidation, or retrieval of memory are rich in ionotropic GABARs. RDL antibody stains structures in the brain of the cricket *A. domesticus* that are associated with learning (Strambi *et al.*, 1998). Particularly dense staining was observed in the mushroom bodies (especially the upper part of the peduncle and the two arms of the posterior calyx) and antennal lobe. Subsequent electrophysiological studies have further provided direct evidence that picrotoxinin sensitive GABARs are present on Kenyon cells of *A. domesticus* (Cayre *et al.*, 1999).

Although it is difficult to determine from immunohistochemical data the exact role that GABAergic neurons play in learning, there are indications that one such role is in providing inhibitory feedback. In the honeybee, *A. mellifera*, 50% of the approximately 110 GABA immunoreactive neurons in the mushroom body appear to be feedback neurons (Grunewald, 1999). Here they connect specific layers of the output regions (α and β lobes and pedunculi) with the input regions (the calyces). In the same species, GABA immunoreactive processes were found to synapse onto fine fibers (70%) and large, non-GABAergic boutons (probably from intrinsic and extrinsic mushroom body neurons, respectively) (Ganeshina and Menzel, 2001). These synapses are components of microcircuits, probably involving feed-forward and feedback loops. Similar microcircuits have been identified in the calyx neuropil of the *D. melanogaster* mushroom body (Yasuyama *et al.*, 2002). Here also, extrinsic GABA immunoreactive neurons appear to form a network of fine fibers codistributed with mainly Kenyon cell dendrites, onto which they make divergent synaptic inputs as well as onto boutons of projection neurons. Each microcircuit takes the form of a glomerulus consisting of a large cholinergic bouton at its core, surrounded by tiny, vesicle-free Kenyon cell

dendrites and input from GABA fibers. The pattern of staining suggests that Kenyon cells receive excitatory input from cholinergic cells along with postsynaptic inhibition from GABA cells.

GABAergic pathways appear also to provide substantial input to, and output from, the mushroom bodies. In the cockroach, *P. americana*, Yamazaki and colleagues (Yamazaki *et al.*, 1998) identified three types of GABA immunoreactive neurons in cockroach mushroom body. The first type consisted of a number of neurons (7–9) that ascended from the circumesophageal connective and projected into the calyces, suggesting that they were input neurons. A second type consisted of a larger number of cells (around 40), with dendrites ramifying in the junction between the pedunculus and the lobes, which are thought possibly to be inhibitory input neurons. Finally, a small number of large cells arborize around the alpha-lobe and project into large areas of calyces.

Mushroom bodies of the cockroach are also known to receive inputs from four giant interneurons, the calycal giants. These, too, are immunoreactive to GABA and input directly onto Kenyon cells. They are spontaneously rhythmically active, and this activity is inhibited by olfactory, visual, tactile, and air current stimuli (Nishino and Mizunami, 1998), and so may play a role in sensitizing Kenyon cells to olfactory stimuli through disinhibition.

Thus, inhibitory pathways are important in insect learning, but lack of functional data has so far precluded a detailed analysis of the different roles of GABARs. However, a number of exciting studies suggest that GABAergic circuits might contribute to the establishment of olfactory memory through the coordination of spike timing. For example, GABA affects the synchronous oscillation of intracellular calcium in Kenyon cells in *Drosophila*, an activity thought to be involved in memory consolidation (Rosay *et al.*, 2001). The possible role of GABARs in this activity is discussed in the following section.

5.4.2.11.2. Stimulus encoding and tuning

5.4.2.11.2.1. Odor representation in the antennal lobes Neurons in the antennal lobes of locusts and honeybees respond to certain odor stimuli (**Figure 8**) with synchronized, oscillatory activity (MacLeod and Laurent, 1996; review: Kauer, 1998). There is ample evidence that GABARs play a key role in the formation of this synchronization. For instance, the injection of GABA antagonists into the first olfactory relay neuropil of locust abolishes synchronization of odor specific neural assemblies in the antennal lobe (MacLeod and Laurent, 1996). Significantly, the temporal response patterns of individual neurons remain unaffected, even though such patterns include some hyperpolarization. Thus, this action of fast, ionotropic GABARs is specific to the formation of synchronization. Similar findings have been reported for the honeybee (review: Kauer, 1998).

The use of optical imaging techniques, such as calcium imaging, and the use of fluorescent, voltage sensitive dyes, allows the activity of large numbers of cells to be monitored simultaneously. In the honeybee, *A. mellifera*, spatiotemporal odor response patterns observed in olfactory glomeruli of the antennal lobes in response to odor stimuli can be mapped to identified glomeruli. By examining the effects of GABA or PTX injection in the antennal lobe, it can be shown that there exist two separate inhibitory networks that render such response patterns more confined, i.e., they enhance their spatial contrast (Sachse and Galizia, 2002). One of these networks is GABAergic and modulates overall antennal lobe activity, and the other is PTX insensitive and glomerulus specific. Confirmation that GABAergic connections underlie such synchronized oscillations is provided by computer simulations. For example, simulations show that GABA synapses forming inhibitory connections between local interneurons and projection interneurons of the antennal lobe allow the formation of dynamic assemblies of neurons, which oscillate together and synchronize transiently (Bazhenov *et al.*, 2001a). Thus, GABA-ergic synapses coordinate the activity of a large number of neurons to produce rhythmic, coordinated firing.

5.4.2.11.2.2. Fine-tuning of odor representation In many insect sensory systems, lateral inhibition serves the role of sharpening stimuli and enhancing the contrast of stimulus representation. In the antennal lobe, odor identity and duration of stimulation are represented both spatially, in the pattern of activity in antennal lobe glomeruli, and temporally, in the pattern of activity in groups of neurons. Spatial encoding is seen in response to electrical stimulation of the antennal nerve in the silkworm moth, *B. mori*, which is followed by postsynaptic depolarizations in the antennal lobe. These depolarizations can be monitored using optical recordings with voltage sensitive dyes (Ai *et al.*, 1998). GABA mediated IPSPs occur in the antennal lobe within 3 ms of these postsynaptic depolarizations, and these IPSPs, like the depolarizations, are not uniform over the antennal lobe, suggesting that the pattern of excitation is specific. GABAergic IPSPs also occur in the macroglomerular complex and some ordinary glomeruli in the antennal lobe. Recent evidence using computer simulations suggests that in the locust

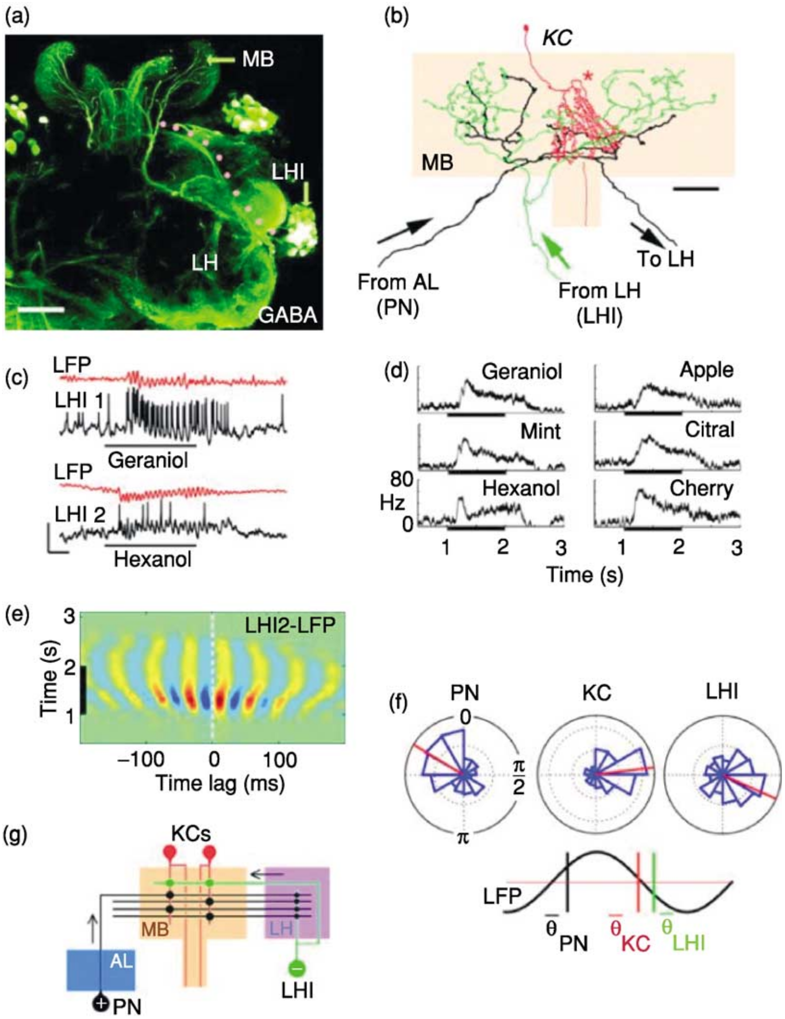

Figure 8 Feed-forward inhibition of KCs by LHIs. (a) Immunolabeling by antibody to GABA (37). Cluster of about 60 reactive somata (LHI) and tract of LHI axons running to the MB (stipples) are shown. The terminals of one of these axons in the MB are shown in (b). Scale bar = 100 μ. (b) PN axon (black) projects to the MB calyx (orange) and to the lateral horn (LH) (41). LHI axon (green) projects to the calyx (this study). PN and LHI axons terminate on KC dendrites (red). Neurons were stained by iontophoresis of cobalt hexamine (KC, PN) or neurobiotin (LHI) in separate preparations and were drawn with a camera lucida. Note varicosities in LHI and PN axon collaterals. Asterisk, KC axon. Scalebar = 50 μ. (c) Representative odor evoked responses of two LHIs and simultaneously recorded LFPs (5 to 40 Hz bandpass). Note membrane potential oscillations, locked to the LFP. Identity and delivery (1 s long) of stimulus indicated by black bar. LHI, 20 mV; LFP, 400 μV; 200 ms. (d) Instantaneous firing rate of LHI1 (in (C)) in response to various odors. Lower edge of profile shows mean instantaneous rate averaged across trials; profile thickness, SD. All LHIs responded to all odors tested, with response profiles that varied little across different odors. (e) Sliding cross-correlation between LFP and LHI2 traces (spikes clipped). Red, maxima; blue, minima. Strong locking is present throughout the response (odor delivery, vertical bar). Lower edge of correlation stripes just precedes stimulus onset due to width of the correlation window (200 ms). (f) Phase relationships between PN, KC, and, LHI action potentials, and LFP. (Upper) Polar plots. LFP cycle maxima defined as 0 rad, minima as π rad (PNs: 3 cell-odor pairs, 388 spikes; LHIs: 17 cell-odor pairs, 2632 spikes; KCs: 18 cells, 862 spikes). Mean phases are shown in red. Gridlines are scaled in intervals of 0.10 (probability per bin). (Lower) Schematic diagram showing LFP and mean firing phases. (g) Circuit diagram. (Reprinted with permission from Perez-Orive, J., Mazor, O., Turner, G. C., Cassenaer, S., Wilson, R.I., **2002**. Oscillations and sparsening of odor representations in the mushroom body. *Science 297*(5580), 359–365.)

these characteristic spatial patterns of activity seen in response to odor stimuli arise from competition among neurons with GABAergic outputs. GABAergic interconnections between local interneurons create competition between them that results in coordinated, phase-locked activity in separate groups of neurons. Thus, GABARs contribute to spatial and temporal patterns of activity that encode the stimulus (Bazhenov *et al.*, 2001b).

In addition to spatial representation of the odor stimulus, temporal synchronization plays a role in odor discrimination, as well as in memory. In

honeybees (Stopfer *et al*., 1997; Hosler *et al*., 2000), block of odor evoked oscillatory synchronization by PTX results in an impairment of discrimination of similar, but not that of dissimilar, odors. This points to a role of synchronization in sharpening odor discrimination.

The circuitry by which GABAergic neurons perform this is unknown. However, in the antennal lobe of the cockroach, *P. americana*, GABAergic neurons form connections that are suggestive of both feedforward and feedback inhibition (Distler *et al*., 1998). In cockroach antennal lobe glomeruli, a major processing center in olfaction, GABAergic local interneurons mediate inhibitory feedback connections onto both antennal receptor neurons and uniglomerular projection neurons. Each GABAergic neuron innervates a large number of antennal lobe glomeruli, thus potentially passing information to neighboring glomeruli (Distler and Boeckh, 1997, 1998). It is presumably these connections between local interneurons and excitatory projection neurons that create the coordinated, distributed oscillations in response to odor stimulation, which, in locusts at least, encode odor identity.

In addition to the identity of an odor stimulus, antennal lobe neurons also encode the duration of the odor. Hence, continuous application of an odor evokes a complex wave of depolarization and hyperpolarization, whereas a pulsatile stimulus evokes a simple train of spikes (Christensen *et al*., 1998). Here again, GABARs play a key role. GABA evoked IPSPs in *M. sexta* projection neurons of the antennal lobe resemble not only electrically evoked IPSPs, but also odor evoked IPSPs. For example, both GABA and odor evoked IPSPs are blocked by bicuculline. At the same time, administration of bicuculline also reversibly alters the temporal pattern of odor evoked activity in the projection neurons, providing circumstantial evidence that GABARs help shape the temporal pattern of activity (Christensen *et al*., 1998). This may also indicate a particular role for the bicuculline sensitive subtype of GABAR.

5.4.2.11.2.3. Involvement of GABA inputs in fine-tuning of sensory pathways may be a general phenomenon In a manner reminiscent of the sharpening of the spatial patterns of odor responses described above, GABAergic inputs appear to be responsible for fine tuning of sensory inputs in other sensory systems. An identified auditory neuron, AN1, of the bushcricket, *Ancistrura nigrovittata*, is finely tuned to the fundamental frequency of the male song. GABA input to this neuron greatly sharpens its selectivity for the fundamental frequency, severely attenuating subthreshold inputs in response to lower, and more so to higher, frequency sounds (Stumpner, 1998). This effect is highly specific in that other inputs through other neurotransmitters are responsible for side and frequency dependent inhibitions.

A similarly striking example is seen in the escape behavior of the cockroach, *P. americana*. Escape responses to wind stimuli are mediated by giant interneurons (Levi and Camhi, 2000), some of which respond selectively to wind from a particular direction, while others are omnidirectional (Buno *et al*., 1981; Westin *et al*., 1988; Okumah and Kondoh, 1996). Those that show a pronounced directional sensitivity respond to wind in a linear manner whereas those that are omnidirectional in their sensitivity respond nonlinearly. The synaptic input onto these cells results in a depolarization followed by a delayed hyperpolarization. This hyperpolarization was blocked by PTX , resulting in an altered response of an identified neuron (Neuron 101) from linear to nonlinear (Okumah and Kondoh, 1996). Hence, GABAergic synapses contribute to the transfer function of these neurons. Furthermore, Hill and Blagburn (1998) demonstrated that the receptive fields of GI6 and GI7 (which means the directional sensitivity) are sharpened by GABA mediated inputs.

GABARs on the terminals of afferent fibers probably also play a major role in the modulation of sensory input through presynaptic inhibition. In the locust, presynaptic inhibition of tegula afferents mediated through GABARs modulates the amplitude of postsynaptic potentials in the hind-wing motor neurons in this monosynaptic pathway in a phase dependent manner (Buschges and Wolf, 1999). GABARs also mediate inhibition by identified filiform hair receptors of an identified projection interneurone in a circuit that mediates wind elicited responses (Gauglitz and Pfluger, 2001). In addition, GABA ergic neurons modulate transmitter release at synapses between the fore-wing stretch receptor and wing depressor motor neurons of *L. migratoria* (Judge and Leitch, 1999). Consistent with this role is the observation that GABARs are distributed over the terminals of primary auditory afferents in certain crickets, and are located near output synapses, again suggesting that they play a role in presynaptic inhibition (Hardt and Watson, 1999).

Clearly, then, GABARs of insects probably play major roles in sharpening receptive fields of various sensory systems, as well as acting at "higher" sensory integration centers in aiding stimulus discrimination and the consolidation of memory.

5.4.2.11.3. Other behaviors involving GABARs While attention has already been drawn to the role for GABARs (presumably including the cloned *Drosophila* GABAR subunit, RDL) in memory

consolidation, the pattern of staining of cockroach brains with an RDL antibody also suggests a wider involvement with olfactory, visual, and mechanosensory processing (Sattelle *et al.*, 2000). In the locust, *S. gregaria*, GABA and GAD immunoreactivity is observed in about 100 bilateral pairs of tangential neurons that connect the lateral accessory lobes to distinct layers of the central body in the central complex, a structure that plays a role in motor control and visual orientation (Homberg *et al.*, 1999).

GABA is not only present in the insect nervous system, but also occurs in the periphery. GABARs have been demonstrated on skeletal muscle of cockroach (Schnee *et al.*, 1997), and those present on the flexor tibiae muscle of locust have received considerable attention (Cull-Candy and Miledi, 1981; Cull-Candy, 1982). GABA also plays a role in visceral functions. For instance, GABA decreases the heart rate of pupal *Drosophila*, although curiously it has no effect upon Hear rate of larval or adult flies (Zornik *et al.*, 1999). GABAergic neurons inhibit the prothoracic gland of *P. americana* up to the 17th day of the molt cycle, after which cessation of their input elicits competence of the prothoracic gland through disinhibition (Richter and Bohm, 1997).

Recent evidence also points to a role of GABAergic neurons in higher levels of behavior. GABA-immunoreactive neurons connect the noduli of accessory medulla to the medulla and to the lamina via processes in the distal tract of the cockroach, *Leucophaea maderae*. Interestingly, the accessory medulla of *D. melanogaster* and of *L. maderae* is thought to be the location of the circadian pacemaker. Injection of GABA into the vicinity of the accessory medulla resets the circadian motor activity of the cockroach in a stable, phase-dependent manner, suggesting that, along with Mas-allatotropin, GABA plays a role in circuits relaying photic information from circadian photoreceptors to the central pacemaker (Petri *et al.*, 2002).

Roles of GABARs in behavior can also be gauged indirectly through alterations in GABA transporter function. Disrupting GABA transporter function *in vivo*, thereby prolonging the effects of GABA at the synapse, in adult female *D. melanogaster* reduced locomotor activity, disrupted geotaxis, and induced convulsions with secondary loss of locomotor activity, without damaging feeding activity or female sexual receptivity (Leal and Neckameyer, 2002).

5.4.3. Metabotropic GABARs of Insects

Very little is known of insect $GABA_B$ (metabotropic) receptors, largely because baclofen is ineffective in many invertebrate preparations (Sattelle *et al.*, 1988; Benson, 1989). However, $GABA_B$-like responses were observed in giant interneurons of the terminal abdominal ganglion of the cockroach (Hue, 1991). Similarly, the motor neuron, D_f, of the same species was thought not to possess $GABA_B$ receptors, until it was shown that responses to $GABA_B$ receptor agonists could be observed when the ionotropic GABARs are blocked by PTX (Bai and Sattelle, 1995). These responses, which appeared to be mediated by a potassium conductance, differed in their pharmacology from vertebrate $GABA_B$ receptors in their insensitivity to baclofen (a property shared by $GABA_B$ responses in the cockroach GI2 and reduced sensitivity to the highly potent vertebrate $GABA_B$ agonist, SK&F97541. It was also shown recently that cultured Kenyon cells of *A. domesticus* possess $GABA_B$ receptors, in addition to PTX sensitive receptors (Cayre *et al.*, 1999). This was soon followed by the cloning, sequencing, and functional expression of $GABA_B$-like receptors from *D. melanogaster.*

5.4.3.1. A Cloned Insect Metabotropic ($GABA_B$) Receptor

Three second-messenger linked, $GABA_B$-like receptors have been cloned from *Drosophila* to date (Mezler *et al.*, 2001). Two of them have high sequence similarity to mammalian $GABA_BR1$ and $GABA_BR2$, whereas the third has no known mammalian counterpart. All three are expressed in the embryonic nervous system, and two are expressed in similar regions and may coexpress *in vivo* to form the functional receptor. R1 and R2 coexpressed in oocytes produce receptors with pharmacology dissimilar to vertebrates in that they are insensitive to baclofen. R3, however, did not produce functional receptors in any combination. These *Drosophila* $GABA_B$ receptors have similar intron positions and exon size to human $GABA_BRs$ (Martin *et al.*, 2001). More detailed physiological, pharmacological, and immunohistochemical experiments are needed in order to establish functional roles for these receptors.

5.4.4. Conclusions

With the cloning of ionotropic insect GABARs, along with detailed immunohistochemical studies and improved optical recording techniques, we have seen remarkable advances in our understanding of insect GABARs over the past 15 years. In addition, the recent cloning of metabotropic GABARs opens up a vast new area of research aimed at establishing the functional role of these receptors in the insect nervous system.

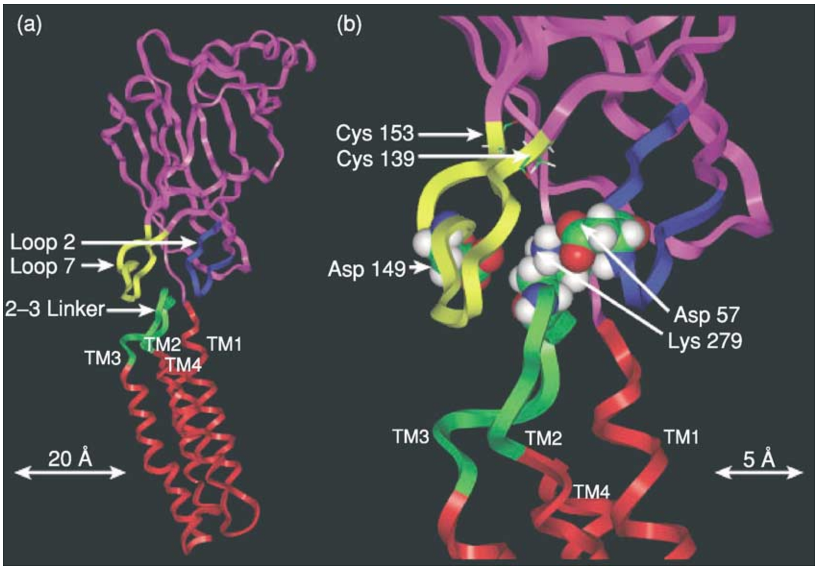

Figure 9 A molecular model of the $GABA_A$ receptor α1 subunit: (a) a model of a whole $GABA_A$ receptor α1 subunit viewed from the center of the ion channel; (b) detailed view of potential contacts between the extracellular and transmembrane domains. (From Kash, T.L., Jenkins, A., Kelley, J.C., Trudell, J.R., Harrison, N.L., **2003**. Coupling of agonist binding to channel gating in the GABAA receptor. *Nature 421*, 272–274.)

Our survey of the more recent findings in the area of insect GABARs leads us to suggest that these receptors are more complex than once was thought, that they form a class distinct from any vertebrate ionotropic GABAR, and that several distinct subtypes exist. Also, a single subunit, RDL, has both alternative splicing and RNA editing. It appears that GABARs play important roles, through inhibition, in stimulus discrimination, receptive field sharpening and memory formation.

Future investigations into this exciting class of neurotransmitter receptors will undoubtedly benefit from the developments in genomics and proteomics to facilitate the study of coexpressed genes and interacting gene products. Other areas that require further attention include the role played by GABARs in insect development, and the specific roles of GABAR subunit variants. The highly tractable development patterns of insects are likely to provide key insights into these strategic questions.

The recently developed technique of double-stranded RNA interference (RNAi) offers some exciting opportunities for future research into insect GABARs. For instance, this approach could be used to assess the roles of GRD and LCCH3, as well as probing further the role of RDL in synaptic transmission, insect learning, sensory tuning, and the circadian clock.

The recent crystal structure of the acetylcholine binding protein (Brjck *et al.*, 2001) now permits homology modeling of the N-terminal domain of a variety of cys-loop neurotransmitter receptors, including insect GABARs. In the future, it will be of interest to attempt molecular modeling of those parts of the RDL extracellular N-terminal domain (see Figure 9) that contribute to the agonist binding sites. This would permit elucidation of the mechanisms by which ligands dock to the four alternative splice variants of RDL to be compared, and introduces the possibility of undertaking parallel site-directed and *in silico* mutagenesis studies. Such a model may be of considerable use in the rational design of a future generation of insecticides incorporating both an improved level of safety and a reduced level of impact on nontarget species.

5.5 Insect G Protein-Coupled Receptors: Recent Discoveries and Implications

Y Park, Kansas State University, Manhattan, KS, USA
M E Adams, University of California, Riverside, CA, USA

5.5.1. Introduction

G protein-coupled receptors (GPCRs) are integral membrane proteins that sense and transduce extracellular signals into cellular responses. The binding of small ligands to the extracellular domains of these proteins elicits a cascade of intracellular responses through activation of heterotrimeric G proteins. In insects, many signaling molecules and their corresponding biological functions have been identified, but knowledge of the signal transduction subsequent to receptor binding has been limited by the relative paucity of information about GPCR structure and function.

It is clear that remarkably diverse physiological processes are mediated by GPCRs. Some of these include sensing of environmental signals such as light, odors, and taste. Others sense extracellular signaling molecules such as calcium, nucleotides, neurotransmitters, biogenic amines, and neuroendocrine peptides. Evolution of GPCRs for specific functions in a vast array of organisms is one interesting area of study, for which insects in many ways are ideal for comparative studies. In addition to their value for basic science, GPCRs mediate vital physiological events in insects that may provide promising targets for development of pest control measures as well as therapeutic targets for promotion of human health.

The advent of the postgenomics era is providing excellent opportunities to explore insect GPCRs and their biological functions. Genomic surveys of GPCRs in the fruit fly *Drosophila melanogaster* and in the malaria mosquito *Anopheles gambiae* have identified at least ~200 and 276 GPCRs, respectively (Brody and Cravchik, 2000; Hill *et al.*, 2002a). Sequence analysis reveals an appreciable degree of groupwise homology relationships between insect and vertebrate GPCRs, suggesting many GPCRs have common ancestry dating more than 600 million years ago (Benton and Ayala, 2003). Data mining combined with functional studies of insect GPCRs has begun to reveal specific ligand–receptor interactions.

Deorphaning insect GPCRs by finding cognate ligands in *Drosophila* is now being followed by expansion of physiological studies in other species of insects that are more amenable to physiological experiments. The use of genomics as a springboard for understanding physiological mechanisms is complemented by advances in molecular probes, genetics, and imaging technologies, leading to a new era of "molecular physiology." This review will cover

recent progress in the molecular and functional characterization of insect GPCRs.

5.5.2. Structure–Function Relationships for GPCRs

GPCRs are characterized by conserved core structures, consisting of an extracellular N-terminus, seven transmembrane (TM) α-helices each connected by alternating extracellular and intracellular loops (e1, e2, e3, i1, i2, and i3), and an intracellular C-terminus. The structure of the seven transmembrane protein bovine rhodopsin revealed by X-ray crystallography epitomizes the generalized bauplan predicted for GPCRs (Palczewski *et al.*, 2000; Teller *et al.*, 2001; review: Filipek *et al.*, 2003) (**Figure 1**). A number of important general structural features emerging from studies of vertebrate GPCRs are worth summarizing here as a prelude to discussions of insect GPCRs. Of course, caution is necessary in extrapolating knowledge from these works directly to other groups of phylogenetically diversified GPCRs.

The location of ligand binding sites varies considerably between different families of GPCRs. Indeed, GPCRs can be broadly categorized according to ligand size and location of the binding site. Such information is critical in the design of candidate drugs with either agonist or antagonist properties. For instance, GPCRs for small ligands such as retinoic acid, odorants, and biogenic amines appear to have a binding pocket surrounded by the TM bundle (Gotzes and Baumann, 1996; Vaidehi *et al.*, 2002). However, ligand binding to other groups of GPCRs involves extracellular epitopes of the protein, including the N-terminus and extracellular loops (Bockaert and Pin, 1999). In the case of the metabotropic glutamate and γ-aminobutyric acid B ($GABA_B$) receptors, the large N-terminus is composed of two lobes arranged for trapping ligands (Hermans and Challiss, 2001). In *Drosophila*, the N-terminal ectodomain of methuselah, an orphan GPCR associated with extended lifespan, consists of three β structure regions, which meet to form a shallow interdomain groove. This region characterized by an exposed tryptophan residue forms a putative ligand binding site by analogy with ectodomains of other GPCRs (West *et al.*, 2001).

The seven TM helices of GPCRs are arranged in an anticlockwise sequential manner when viewed from the extracellular aspect (**Figure 1**). Ligand binding induces changes in core structure, and in particular TM3 is thought to have a major role in receptor activation by altering the relative orientation of TM6 (Bockaert and Pin, 1999). Likewise, the conserved tripeptide signature of the TM3 cytoplasmic interface ([D,E]R[Y,W]) is considered to be important in receptor activation. The TM helices often are interrupted by distortions of the α-helix backbone, which may serve as hinge points

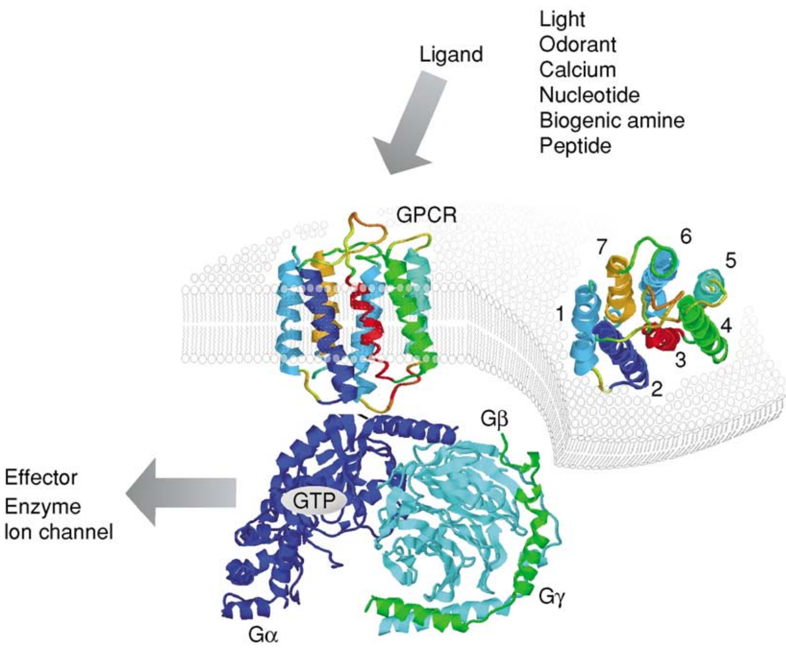

Figure 1 A diagram summarizing G protein-coupled receptor (GPCR) signaling. An array of seven transmembrane segments is shown according to the bovine rhodopsin structure. The trimeric G protein consisting of Gα, Gβ, and Gγ is coupled to the GPCR. Activation of the GPCR by ligands binding to the extracellular cell surface is amplified by intracellular effector proteins.

underlying conformational changes induced by ligand binding.

The cytoplasmic face of GPCRs interacts with heterotrimeric G-proteins, which dissociate upon receptor activation to trigger specific signal transduction pathways (**Figure 1**). Specificity for particular subtypes of heterotrimeric G-proteins is an important factor in determining downstream pathways. The *Drosophila* genome presents at least seven genes encoding Gα, six for Gβ, and two for Gγ subunits. The subunit Gα is in direct contact with the cytoplasmic interface of GPCRs (Bourne, 1997; Wess, 1998; Horn *et al*., 2000; Moller *et al*., 2001). Prediction of G protein subtype coupling specificity has been attempted in vertebrate GPCRs through identification of characteristic cytoplasm-facing sequence motifs (Bourne, 1997; Wess, 1998; Horn *et al*., 2000; Moller *et al*., 2001). This is a nontrivial exercise, considering reports showing GPCRs coupled with multiple G proteins as well as agonist-dependent changes in GPCR coupling with different G proteins (Robb *et al*., 1994; Reale *et al*., 1997; Cordeaux *et al*., 2001; Cordeaux and Hill, 2002).

Proper functioning of GPCRs often may depend on oligomerization with other proteins (Gomes *et al*., 2001; Angers *et al*., 2002). Such interactions may serve to localize receptors for effective coupling with downstream pathways and/or to influence desensitization, which regulates receptor levels on the cell surface and temporal parameters of the biological response (Pierce and Lefkowitz, 2001; Brady and Limbird, 2002; Kohout and Lefkowitz, 2003).

5.5.3. Evolution of Insect GPCRs

In a pioneering study, Hewes and Taghert (2001) performed a comprehensive phylogenetic analysis of *Drosophila* peptide GPCRs covering the entire array of annotated genes in the *Drosophila* genome. The analysis revealed 42 putative peptide GPCRs arranged within 15 monophyletic subgroups together with vertebrate peptide GPCRs. The relationships established in this study also appear to be valid generally for the *Anopheles* mosquito (Hill *et al*., 2002a). Evolutionary relationships between *Drosophila* and vertebrate peptide GPCRs have provided impetus for formulation of hypotheses to guide the process of deorphaning insect GPCRs. The success of this approach has been enhanced by many instances of previously established vertebrate ligand–receptor relationships. As this process advances, coevolutionary relationships between peptide GPCRs and their ligands have been brought into clearer focus.

Ligand–receptor coevolution has occurred as a consequence of reciprocal evolutionary influences between two interacting proteins – ligand and receptor – while the original definition of coevolution emphasized interactions between organisms (see Ridley, 1993). Assuming GPCRs share a common ancestral gene, diverse GPCRs must have arisen through multiple steps of gene duplication types of evolutionary processes (Chothia *et al*., 2003). In phylogenetic analyses, closely related GPCRs have cognate ligands also related each other, indicating that an ancestral ligand–receptor partnership has effectively rooted new sets of ligand–receptors with a novel function. The ligand–receptor partners appear to be maintained during evolution without punctuated changes of their relationships; thus coevolution may be a common phenomenon.

In the coevolution of ligand–receptor partners, it has been proposed that divergence of the receptor precedes the evolution of its cognate novel neuropeptide ligand (Darlison and Richter, 1999). Such reasoning is based on the frequent occurrence of multiple receptors for a single peptide. This hypothesis, however, may be questioned because many peptide encoding genes have multiple repeats of isopeptides and processing sites. A good example is the tetrapeptide FMRFamide, for which eight homologous repeats appear in the *Drosophila* propeptide gene (Schneider and Taghert, 1988, 1990). There also appears to be a significant degree of flexibility in the system, evidenced first by the presence of multiple receptors for a given ligand that are coupled to different G proteins (Darlison and Richter, 1999; Park *et al*., 2003) and second by differential selectivity of receptors to a number of isopeptides (Darlison and Richter, 1999). Further details regarding processes of ligand–receptor coevolution can be found in a number of recent publications (van Kesteren *et al*., 1996; Darlison and Richter, 1999; Goh and Cohen, 2002).

While discerning evolutionary relationships among GPCRs is challenging, establishing such relationships for signaling peptides is a much more daunting task. The main problem lies in the fact that only a small number of functionally important, conserved amino acids within peptide sequences defines their evolutionary relationships. A valuable search tool in bioinformatics, the position-specific iterated BLAST (PSI-BLASAT: Altschul *et al*., 1997), provides a powerful means of using small short, conserved sequence motifs for searching distantly related peptides. The method uses a score matrix generated from multiple alignments of the highest scoring hits in each round of the search. Conservation of consensus amino acids in the multiple

sequence alignment implies functionally and evolutionarily important amino acid residues common for a group of signaling peptides.

A good example of ligand–receptor coevolution was found for a group of neuropeptides having a C-terminal PRXamide motif (Pro-Arg-Xxx with C-terminal amide). This motif is common to an array of peptides occurring in both insects and vertebrates, including neuromedin U (NMU), cardioacceleratory peptide 2b (CAP2b), pyrokinins, and ecdysis triggering hormone (ETH). This group of peptides activates a cluster of GPCRs related to vertebrate receptors for NMU and thyrotropin releasing hormone (Park *et al.*, 2002) (**Figure 3**). While phylogenetic relationships among receptors are established almost exclusively on the basis of amino acid sequence, the patterns of pharmacological cross-reactivity for these GPCRs to cognate PRXamide peptides provide a new and "functional" criterion for inferring evolutionary relationships for ligand–receptor pairs.

Despite the frequent correspondence of insect and vertebrate ligand–receptor relationships, a number of *Drosophila* GPCRs are found to be relatively unique (Hewes and Taghert, 2001), such as *Drosophila* GPCRs having bootstrap values of less than 300 in 1000 pseudosamples. For example, closely related GPCRs within the group CG13229, CG13803, and CG8985 are found to have no significant relationship with other vertebrate GPCRs. Recently, two of these receptors CG13803 and CG8985 were found to be activated by Dromyosuppressin (Johnson *et al.*, 2003a; Egerod *et al.*, 2003a) having the C-terminal motif FLRLamide, a member of FMRFamide-related peptides (FaRPs) containing a C-terminal RFamide. Such unique GPCRs could arise either through rapidly evolving branches of GPCRs, or through recent loss of the related GPCRs in the vertebrates.

5.5.4. Insect GPCRs

5.5.4.1. Classification of GPCRs

Classification of the GPCR superfamily by families and groups has been made based on a combination of natural ligand categories and receptor sequence homology (Kolakowski, 1994; Horn *et al.*, 2000; Hewes and Taghert, 2001). For the following discussions, these classifications are used to cover comprehensive categories of GPCRs in all organisms. Accordingly, insect GPCRs are classified into the following families: family A, rhodopsin and various peptide receptors; family B, secretin-like peptide receptors and methuselah (mth); family C, metabotropic glutamate receptors, atypical GPCRs such as

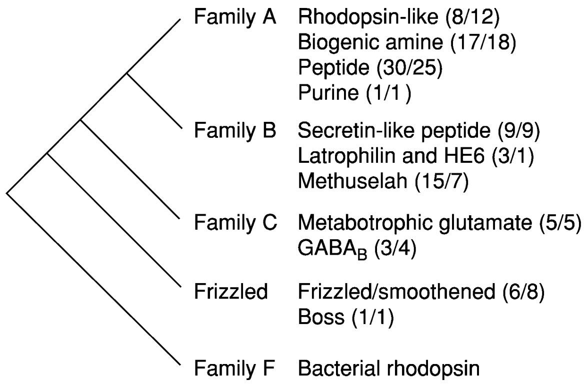

Figure 2 A conceptual phylogenetic relationship of the GPCR superfamily. The numbers of annotated genes for *Drosophila* (left) and *Anopheles* (right) are in parentheses. The conceptual tree is still not congruent and reconstructed based on Josefsson (1999).

frizzled/smoothened and bride of sevenless (boss), and odorant receptors (**Figure 2**).

Assuming all groups of GPCRs (or 7-TM proteins) are ancestrally related, a conceptual tree depicting evolutionary relationships among them can be drawn based on combined results from previous studies (**Figure 2**), while construction of a congruent tree is still controversial because of its high sequence divergency (Josefsson, 1999). The number of *Drosophila* genes encoding putative GPCRs as a fraction of the total in each group is shown in parenthesis for each category (**Figure 2**). In rooting the tree on family F, which includes bacterial rhodopsin, the group frizzled appears to be the most ancestral form. Family A with ~90 GPCRs is the largest group, and includes biogenic amines, peptides, rhodopsin, and ~30 orphan receptors (Hill *et al.*, 2002a). Given the excellent phylogenetic analysis for *Drosophila* peptide receptors in the previous study (Hewes and Taghert, 2001). We provide **Tables 1–3** summarizing the GPCRs that have been cloned so far. This table includes *Drosophila* data and GPCRs from other insects, but not the GPCRs of *A. gambiae* where experimental data is unavailable.

5.5.4.2. Family A: Biogenic Amine, Rhodopsin, and Neuropeptide Receptors

5.5.4.2.1. Biogenic amine receptors Most small signaling molecules used as transmitters, modulators, and hormones are common to vertebrates and invertebrates, including insects. The most prominent are acetylcholine, glutamate, GABA, and the biogenic amines serotonin, dopamine, and histamine (**Table 1**). Norepinephrine and epinephrine, abundant in the vertebrates, are absent or present only in very low amounts in insects (Maxwell *et al.*,

Table 1 Insect G protein-coupled receptors for biogenic amines

Name	*Synonym (GenBank accession number)*	*Species*	*Cellular response (expression system)*	*Expression pattern*	*Reference*
Serotonin receptor					
5-HT2	CG1056, 5HT-dro1, 5HT2dro, Dm5HT2 (X81835)	*Drosophila melanogaster*		Coexpression with pair-rule gene *ftz* in embryo	Colas *et al.* (1999, 1995)
5HT7	CG12073, 5HT-dro1, 5HT7dro, Dm5HTdro1, 5HT-R1 (M55533)	*Drosophila melanogaster*	Increased cAMP (Sf9, NIH 3T3)	Adult head, larval ventral ganglion	Witz *et al.* (1990), Saudou *et al.* (1992), Obosi *et al.* (1996)
5-HT1A	CG16720, 5HT-dro2A (Z11489)	*Drosophila melanogaster*	Inhibition cAMP (COS-7)	Ventral unpaired median neurons	Saudou *et al.* (1992)
5-HT1B	CG15113, 5HT-dro2B (Z11490)	*Drosophila melanogaster*	Inhibition cAMP (COS-7)	Larval ventral ganglion	Saudou *et al.* (1992), Obosi *et al.* (1996)
CG8007	(AE003679, AAN13390)	*Drosophila melanogaster*			Brody and Cravchik (2000)
Aedes 5-HT7	(AF296125)	*Aedes aegypti*		Malpighian tubules, tracheolar cells	Pietrantonio *et al.* (2001)

MabOcR	(AAK14402)	*Mamestra brassicae*			

1978; Evans, 1980). Prominent amines in insects and crustaceans are octopamine and tyramine (Evans, 1980). Octopamine is thought to play a modulatory role in arousal, paralleling that of noradrenaline in the sympathetic system of vertebrates (Evans, 1993; Blenau and Baumann, 2001). Octopamine and tyramine, while only present as "trace amines" in the vertebrates, may nevertheless play functional roles (Borowsky *et al.*, 2001). Among the biogenic amines known to be signaling molecules in insects, histamine is so far the only one for which GPCRs are unknown; electrophysiological data provide conclusive evidence for gating of ionotropic receptors by histamine. This contrasts with histamine receptors in the vertebrates, where both ionotropic and GPCR receptors are known (Roeder, 2003).

The evolutionary patterns of biogenic amine receptors among vertebrates and invertebrates are generally in accordance with monophyletic ancestries (Roeder, 2002), although recent gene duplication events have led to rapid expansions of certain vertebrate receptor groups. Furthermore, there are apparent shifts in ligand specificity in a number of receptor phylogenies, for which the ligands are structurally similar. This phenomenon is particularly apparent for *Bombyx* and *Heliothis* octopamine receptors, which occur in a monophyletic clade with tyramine receptors (Blenau *et al.*, 1998; Ebert *et al.*, 1998; Roeder, 2002).

Numerous functions of biogenic amines in insects are described at the behavioral and physiological levels, including modulation of sensory input and motor output, learning and memory, development, and elevated states of arousal (Blenau and Baumann, 2001; Roeder, 2002). Modulation of olfactory and visual stimuli is indicated by expression patterns of amines in sensory lobes, and by physiological experiments. For example, sensitization of pheromone receptor cells by octopamine and serotonin is indicated in *Bombyx mori* and *Manduca sexta* (Pophof, 2000; Dolzer *et al.*, 2001), and a possible role for serotonin in feedback from higher centers in the brain is indicated from morphological studies (Hill *et al.*, 2002b). Octopamine plays a major hormonal role in energy metabolism during locust flight by acting directly on the fat body and indirectly through release of adipokinetic hormone (Orchard *et al.*, 1993). Setting the day state in circadian cycling by serotonin is suggested for a cricket (*Gryllus bimaculatus*) (Saifullah and Tomioka, 2002), and dopamine receptors are thought to be targets of circadian modulation (Andretic and Hirsh, 2000). Egg diapause in *B. mori* appears to be controlled by dopaminergic pathways in the mother (Noguchi and Hayakawa, 2001).

In a growing number of cases, biogenic amine receptor-specific functions are reported. The *honoka* mutant in *Drosophila* carries a tyramine receptor defect and shows reduced responses to repellent odors. In addition, this mutant exhibited reduced tyramine modulation at the neuromuscular junction, while normal modulation by octopamine was observed (Kutsukake *et al.*, 2000). A role for the serotonin receptor subtype 5-HT2 in embryonic development was shown by a *Drosophila* mutant (Colas *et al.*, 1995, 1999). In these studies, serotonin signaling was found to be necessary for increased

Table 2 Insect G protein-coupled receptors for neuropeptides: family A group III and group V, and family B

cell adhesiveness required for cell–cell intercalation during gastrulation. Expression patterns of the serotonin 5-HT7-like receptor in *Aedes* Malpighian tubules and tracheolar cells are suggestive of possible functions in the control of diuresis and respiration (Pietrantonio *et al.*, 2001).

5.5.4.2.2. Rhodopsin Rhodopsins are a class of retinal-binding chromophores widespread in visual cells of animals. In each rhodopsin, the light-absorbing retinal binds to a pocket within the seven-transmembrane opsin protein. Incoming photons induce isomerization of retinal, which passes protons to its partner opsin, resulting in G protein activation. The eyes of insects are tuned to specific spectral ranges through diversity in genes encoding the opsin structure, whereby amino acid sequence variability occurs in the vicinity of the retinal binding pocket. The coupling of opsins to G-proteins leads to visual transduction through the opening or closing of cation channels in the visual cell. The evolution of genes encoding rhodopsins with different spectral properties have been described in various insect species (review: Briscoe and Chittka, 2001).

The insect compound eye is composed of cartridges called ommatidia, each organized as a set of eight photoreceptor retinula cells (R1–R8). In *Drosophila,* the compound eye expresses seven rhodopsin genes (*Rh1–Rh7*), which show unique expression patterns and spectral properties. A specialized portion of the plasma membrane in each retinula cell is convoluted via microvilli to form the rhodopsin-rich rhabdomere. The rhabdomere of each retinula cell faces the others within the cartridge to create the composite rhabdom, where light is absorbed. Rhodopsin Rh1, also called ninaE (neither inactivation nor after potential E), is expressed in retinula cells R1–R6 (O'Tousa *et al.*, 1985; Feiler *et al.*, 1988). Rh2 is expressed in ocelli (Cowman *et al.*, 1986), simple eyes located on the vertical side of the head, while Rh3 and Rh4 are expressed in R7 in nonoverlapping subsets of ommatidia (Fryxell and Meyerowitz, 1987). Rh5 and Rh6 are expressed in R8 in nonoverlapping subsets of ommatidia (Chou *et al.*, 1996, 1999). Rh7 (CG5638) has been identified in the genome sequence, but has not been associated with a physiological function as yet (Brody and Cravchik, 2000).

Insect rhodopsins are classified generally into three categories according to their responsiveness to ultraviolet, blue, and green colors (Townson *et al.*, 1998). In some cases, rhodopsins sensitive to red color have been identified in the Lepidoptera and Hymenoptera (Briscoe and Chittka, 2001), where adaptive evolution appears to have taken place through replacement of amino acids adjacent to the retinal binding site and thus shifting the spectral sensitivity (Briscoe, 2002). Recent expansions of the rhodopsin gene in different species of insects are observed in the phylogenetic relationships among rhodopsins in the orders Hymenoptera, Diptera, and Lepidoptera (Montell, 1999; Salcedo *et al.*, 1999; Briscoe, 2001; Briscoe and Chittka, 2001; Hill *et al.*, 2002a).

The phototransduction cascade in invertebrates begins with light-absorbing rhodopsin coupled to G_q. This activates phosphoinositide turnover through activation of phospholipase C β (PLCβ), liberation of inositol trisphosphate (IP3), and the opening of transient receptor potential (TRP) channels, leading to inward cation (Na^+ and Ca^{2+}) flux and depolarizing potentials in retinula cells (Alvarez *et al.*, 1996; Montell, 1999; Bahner *et al.*, 2000; Hardie and Raghu, 2001). Invertebrate phototransduction contrasts with that of vertebrates, where at low light intensities a large "dark current" flows through cyclic guanidine monophosphate (cGMP) nucleotide gated sodium channels to maintain a relatively depolarized state (approximately −40 mV). Under dark conditions, photoreceptor cells maintain high levels of cytosolic cGMP and hence a high number of open cyclic nucleotide gated sodium channels. Light absorbance by rhodopsin activates the G protein transducin (G_t), leading to elevation of phosphodiesterase, destruction of cGMP, and consequent closing of sodium channels (Shichida and Imai, 1998). Through this

mechanism, vertebrate photoreceptors hyperpolarize in response to light stimuli.

5.5.4.2.3. Neuropeptide receptors in family A Neuropeptides are ubiquitous signaling molecules acting mainly through GPCRs for activation of cellular responses. Numerous signaling peptides in insects have been characterized by their abilities to activate visceral activity, heartbeat, or glandular secretion (reviews: Gäde *et al*., 1997; Nassel, 2002). Studies of neuropeptide signaling have been accomplished mainly in large insects where biochemical studies and physiological assays are relatively easy. Subsequent findings of neuropeptides in various species show that amino acid sequences of neuropeptides are generally well conserved. With the opening of the postgenomic era, genomic sequences in *Drosophila* and *Anopheles* revealed more than 23 and 35 genes, respectively, encoding neuropeptides (Hewes and Taghert, 2001; Riehle *et al*., 2002). Peptidomics of the central nervous system (CNS) of *Drosophila* (Baggerman *et al*., 2002) identified 28 neuropeptides including eight novel peptides using capillary liquid chromatography in conjunction with tandem mass spectrometry.

Studies of neuropeptide receptors in vertebrates have identified a large number of GPCRs grouped as family A with rhodopsins and biogenic amine receptors (Kolakowski, 1994). Phylogenetic analysis of *Drosophila* and *Anopheles* genome sequences for putative GPCRs revealed ~40 GPCRs in family A in each species (Hewes and Taghert, 2001; Hill *et al*., 2002a). Analysis of phylogenetic relationships revealed that many insect neuropeptide receptors occur in monophyletic groups with vertebrate receptors, implying evolution from common ancestors in each group (Hewes and Taghert, 2001; Hill *et al*., 2002a). Family A is further classified into several subgroups, and insect peptide GPCRs currently are placed into group III or group V (Kolakowski, 1994; Hewes and Taghert, 2001).

Numerous insect GPCRs in family A group III and group V have been cloned and expressed, and functional assays have been key to identification of their ligands (**Table 2**). The earliest efforts to clone neuropeptide GPCRs started with cDNA library screenings that targeted *Drosophila* homologs of the vertebrate neuropeptide Y and tachykinin receptors (Li *et al*., 1991, 1992; Monnier *et al*., 1992). Following identification of these receptors in *Drosophila*, subsequent investigations located their homologs in the stable fly (*Stomoxys Calcitrans*) and cockroach (Leucophaea maderae) (Guerrero, 1997; Torfs *et al*., 2000, 2001, 2002a; Johard *et al*., 2001).

Recent approaches in functional genomics have contributed to the deorphaning of a large number of insect GPCRs. Functional analyses have been designed for screening sets of GPCRs and ligands belonging to a phylogenetic clade. This approach assumes ligand–receptor coevolution (see Section 5.5.6) and utilizes an established ligand–receptor pair as a baseline for formulation of testable hypotheses.

Such an approach was taken to identify likely receptors for peptide ligands having C-terminal PRXamide motifs (Park *et al*., 2002). The PRXa peptides in *Drosophila* and other insects fall into three classes: pyrokinins including the pheromone biosynthesis activating neuropeptide (PBAN) (–FXPRXa) (Raina *et al*., 1989; Matsumoto *et al*., 1990), cardioactive CAP2b-like peptides (–FPRXa) (Morris *et al*., 1982; Huesmann *et al*., 1995), and ETHs (–PRXa) (Zitnan *et al*., 1996; Adams and Zitnan, 1997; Park *et al*., 1999, 2002). In the vertebrates, PRXa motifs are found in the peptides NMU, vasopressin (AVP), and pancreatic polypeptide (PP), for which receptors already have been identified (Thibonnier *et al*., 1994; Fujii *et al*., 2000; Howard *et al*., 2000). Functional analyses demonstrated that *Drosophila* GPCRs related to the monophyletic NMU receptor group are activated by all three classes of *Drosophila* PRXa peptides (**Figure 3**). PRXa receptors are now being investigated in other species of insects, such as *Manduca*, where the physiological functions of the neuropeptides are better characterized (Kim and Adams, unpublished data), while genuine functions of the PRXamide receptors in *Drosophila* also are being investigated.

Drosophila GPCRs related to the vasopressin receptor failed to respond to PRXa peptides, but instead was activated by crustacean cardioactive peptide (CCAP), corazonin, and adipokinetic hormone (AKH), none of which falls into the PRXa peptide group (Park *et al*., 2002). *Drosophila* sulfakinin receptors also were identified through the logic of ligand–receptor coevolution upon finding homology in ligands between vertebrate cholecystokinin/gastrin and *Drosophila* sulfakinin (Kubiak *et al*., 2002). A *Drosophila* neuropeptide F receptor was identified, and found to belong to one of four *Drosophila* GPCRs in the neuropeptide Y receptor subgroup (Garczynski *et al*., 2002; Mertens *et al*., 2002).

Another productive approach for deorphaning GPCRs is reverse physiology (see Section 5.5.5). Receptors for allatostatin type A (DAR-1) (Birgul *et al*., 1999) and allatostatin type C (Drostar1, Drostar2) (Kreienkamp *et al*., 2002a) were identified through isolation from tissue extracts of native

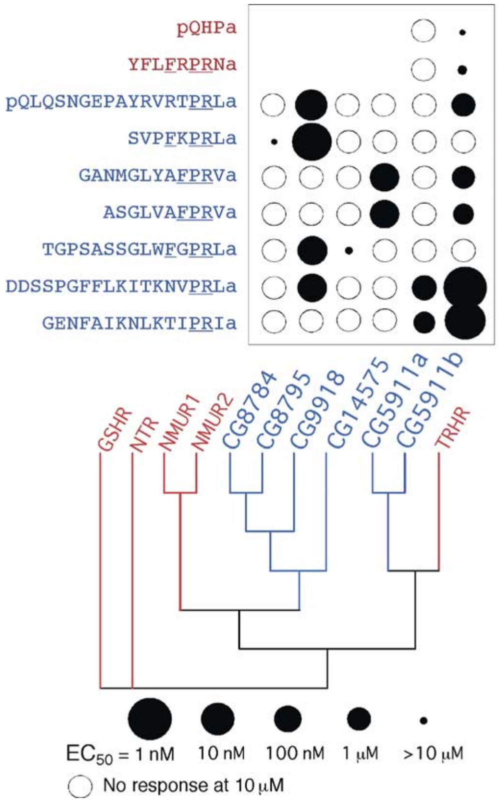

Figure 3 Ligand–receptor specificity for *Drosophila* PRXamide and related peptides. The amino acid sequence of each ligand is shown at the left, with the names of each peptide on the right. Circles indicate relative activity of ligands to each receptor. The larger the circle, the more potent is the peptide. Empty circles indicate ''no response'' at concentrations up to 10 μM, the highest concentration tested. The tree and names of neuropeptide receptors are: GSHR, GH secretagogue receptor; NTR, neurotensin receptor; NMUR1, neuromedin U receptor 1; NMUR2, neuromedin U receptor 2; TRHR, thyrotropin releasing hormone receptor; *Drosophila* PRXamide receptor GPCRs with CG numbers. Red letters are vertebrate peptides and GPCRs. Blue letters are *Drosophila* PRXamide peptides and GPCRs. (Data from Park, Y., Kim, Y.J., Adams, M.E., **2002**. Identification of G protein-coupled receptors for *Drosophila* PRXamide peptides, CCAP, corazonin, and AKH supports a theory of ligand–receptor coevolution. *Proc. Natl Acad. Sci. USA 99*, 11423–11428; and Park, Y., Kim, Y.J., Dupriez, V., Adams, M.E., **2003**. Two subtypes of ecdysis triggering hormone receptor in *Drosophila melanogaster*. *J. Biol. Chem. 278*, 17710–17715).

neuropeptide ligands that activate the receptor. Closely related genes in *Drosophila* and other insect species subsequently cloned and expressed, and showed their sensitivity to related allatostatin peptides (Lenz *et al.*, 2000, 2001; Auerswald *et al.*, 2001; Larsen *et al.*, 2001; Secher *et al.*, 2001). The reverse physiology approach also was successfully employed in identification of the *Drosophila* FMRFamide receptor (Meeusen *et al.*, 2002) and the leucokinin receptor in the snail *Lymnaea* (Cox *et al.*, 1997). Subsequent searches for leucokinin receptor orthologous genes in insects led to identification of novel leucokinin receptors in the cattle tick, *Boophilus microplus* (Holmes *et al.*, 2000, 2003) and in *Drosophila* (Radford *et al.*, 2002).

A gene homologous to the adenosine-like receptor has been found in both *Drosophila* and *Anopheles* genomes (Brody and Cravchik, 2000; Hill *et al.*, 2002a), but biological data are unavailable as yet. The findings in *Drosophila* will facilitate GPCR studies in other arthropod species where biological functions of those neuropeptides have been well characterized (see Section 5.5.5).

5.5.4.3. Family B: Secretin-Like Receptors

Insect GPCRs belonging to family B consist of secretin-like receptors (five genes in *Drosophila*) (**Table 3**), the *methuselah* group (∼11 genes), human epididymis-specific protein 6 (HE6; two genes), and latrophilin (one gene) (Brody and Cravchik, 2000; Hewes and Taghert, 2001; Hill *et al.*, 2002a). Two insect neuropeptides, diuretic hormone and amnesiac (Feany and Quinn, 1995; Zhong, 1995; Zhong and Pena, 1995), are similar to corticotropin releasing factor (CRF) and the pituitary adenylate cyclase activating peptide (PACAP), respectively, of vertebrate neuropeptides that are grouped with receptors in the family B. All five secretin-like receptors in the *Drosophila* family B (Brody and Cravchik, 2000; Hewes and Taghert, 2001) appear to have orthologs in the *Anopheles* genome (Hill *et al.*, 2002a).

The first receptor for an insect diuretic hormone (DH-R) was identified by screening a *Manduca* expression library with a tritiated ligand (Reagan, 1994). The sequence of the *Manduca* DH-R revealed that it is an ortholog of the vertebrate CRF receptor (Hewes and Taghert, 2001). Activation of the *Manduca* DH-R receptor expressed in COS-7 and Sf9 insect cells triggered cAMP elevation (Reagan, 1995). An orthologous gene from the house cricket, *Acheta domesticus*, was cloned and characterized in a functional expression system (Reagan, 1996). The orthologous *Drosophila* DH-R sequence reveals two closely related genes as candidates (CG32843 and CG4395), but no experimental evidence has appeared as yet.

The *methuselah* (*mth*) group of receptors, found by screening for *Drosophila* mutants with extended lifespan (Lin *et al.*, 1998), comprises a large group of GPCRs unique to insects. Phylogenetic analysis of the closely related species *A. gambiae* and *D. melanogaster* revealed recent expansions in the number of copies of the *mth* genes (Hill *et al.*, 2002a). Examination of *Drosophila mth* mutants suggested that

this gene product controls synaptic efficacy at the glutamatergic neuromuscular junction by increasing the rate of neurotransmitter exocytosis from the presynaptic terminal (Song *et al.*, 2002). The crystal structure of the *mth* ectodomain revealed potential ligand binding features in a shallow interdomain groove, although the ligand(s) have yet to be identified (West *et al.*, 2001).

Two genes encoding the GPCRs grouped with the human epididymis-specific protein 6 (HE6) were identified in *Drosophila*, but not in *Anopheles* (Brody and Cravchik, 2000; Hill *et al.*, 2002a). This receptor in vertebrates has an unusually long extracellular region characteristic of cell adhesion proteins, indicating potential roles in cell adhesion and signaling (Stacey *et al.*, 2000; Kierszenbaum, 2003). The genomes of *Drosophila* and *Anopheles* each have genes orthologous to vertebrate latrophilin. Vertebrate latrophilin is a putative receptor or binding protein for α-latrotoxin, a major component of black widow spider (genus *Lactrodectus*) venom. It appears to be involved in triggering calcium independent exocytosis, thus is also known as CIRL (calcium-independent receptor for α-latrotoxin) (Henkel and Sankaranarayanan, 1999). Latrophilin is thought to be a component of a large NMDA-receptor-associated signaling complex (Kreienkamp *et al.*, 2002b).

5.5.4.4. Family C: Metabotropic Glutamate Receptor and GABA$_B$ Receptor

Along with its well-known role in excitatory neuromuscular transmission, the neurotransmitter glutamate mediates both excitation and inhibition within the insect CNS (Parmentier *et al.*, 1998; Washio, 2002). Likewise, GABAergic inhibitory transmission occurs both in the peripheral and central nervous systems. In the CNS, these transmitters mediate both fast and slow transmission via ionotropic and metabotropic receptors, respectively. While our understanding of glutamate and GABA transmission in invertebrates is derived mostly from work on ionotropic receptors, metabotropic receptors are receiving increased attention because of new information gathered from genome sequences.

Analysis of the *Drosophila* genome revealed two genes encoding putative metabotropic glutamate receptors (mGluR) and three genes for metabotropic GABA$_B$ receptors, along with two other related genes not yet annotated (Brody and Cravchik, 2000). The *Anopheles* genome shows orthologous relationships with corresponding *Drosophila* genes in this group (Hill *et al.*, 2002a).

Drosophila mGluR receptors appear to function in the CNS by coupling to G$_i$, inhibiting activation of adenylyl cyclase (Parmentier *et al.*, 1996, 1998), although linkage to K^+ and Ca^{2+} channel modulation downstream could serve excitatory roles as well.

GABA is a major inhibitory neurotransmitter in the CNS of both vertebrates and invertebrates. Postsynaptic, ionotropic GABA$_A$ and GABA$_C$ receptors mediate fast inhibitory responses, while slow transmission occurs via metabotropic GABA$_B$ receptors. In vertebrates, GABA$_B$ receptors mediate reduction of transmitter release presynaptically (Slesinger *et al.*, 1997) and hyperpolarization postsynaptically (Isaacson and Vitten, 2003). Pharmacological studies of the GABA$_B$ receptor in the cockroach *Periplaneta americana* demonstrated hyperpolarizing, ionotropic responses of the fast coxal depressor motor neuron (Bai and Sattelle, 1995).

Heterodimerization of GABA$_B$R1 and R2 subunits is necessary for constitution of a functional receptor in vertebrates (Jones *et al.*, 1998; Kaupmann *et al.*, 1998; White *et al.*, 1998). Furthermore, it is proposed that ligand binding involves only the GABA$_B$R1 subunit (Kniazeff *et al.*, 2002). Orthologous relationships of the subtypes GABA$_B$R1 and R2 are extended to *Drosophila* and the nematode *Caenorhabditis elegans* (Kniazeff *et al.*, 2002). As in the vertebrates, functional *Drosophila* GABA$_B$ receptors require heterodimerization of GABA$_B$R1 and R2 subunits (Mezler *et al.*, 2001). A third *Drosophila* subunit, GABA$_B$R3, appears to be an insect-specific subtype expressed in the CNS.

5.5.4.5. Other GPCRs: Odorant Receptor, Gustatory Receptor, Atypical 7TM Proteins

Analysis of genomic sequences in *Drosophila* and *Anopheles* indicates that the largest groups of GPCRs in insects are odorant and gustatory receptors (~70 genes for each) (Clyne *et al.*, 1999, 2000; Scott *et al.*, 2001; Hill *et al.*, 2002a). These receptors appear to have evolved quickly and comprise largely divergent subgroups having little if any conserved amino acid sequences in most cases. Evidence for functionality as odorant receptors has been provided by heterologous expression and bioassay (Stortkuhl and Kettler, 2001; Wetzel *et al.*, 2001). A gustatory receptor sensing trehalose was identified from a *Drosophila* mutant (Ishimoto *et al.*, 2000; Dahanukar *et al.*, 2001). Homology based cDNA library screening led to cloning of a number of putative odorant receptors in *Heliothis virescens*, and to demonstration of tissue-specific expression in antennae. This work thus has expanded olfactory receptor studies from *Drosophila* to other insect species (Krieger *et al.*, 2002).

Another group of putative receptors having seven transmembrane topology is classified separately as

"atypical 7TM proteins." This class includes frizzled (*fz*), smoothened, and bride of sevenless (bos), most of which were initially identified as *Drosophila* mutants. The function of *fz*, four homologous copies of which are found in *Drosophila* and *Anopheles*, appears to be in establishing morphogenic symmetry and cell polarity during development (Bhanot *et al.*, 1999; Strutt, 2001).

5.5.5. Intracellular Signaling Pathways Triggered by GPCRs

Activation of GPCRs by extracellular ligands at the cell surface leads to a rich diversity of intracellular signal transduction pathways, beginning with activation of heterotrimeric guanine nucleotide-binding proteins (G-proteins), comprised of α, β, and γ subunits (**Figure 1**). The α subunit binds guanosine nucleotides, GDP in the resting state and GTP following activation of the GPCR with which the G-protein is associated. Upon GPCR activation, GTP binding to the α subunit of the G-protein leads to dissociation of the α and βγ subunits. The βγ dimer does not dissociate further under physiological conditions. Both α and βγ subunits can bind independently to target proteins to initiate cellular responses.

The type of intracellular signaling that ensues GPCR activation depends on the associated G protein, most importantly the Gα subunit. Coupling with $G\alpha_s$ activates adenylyl cyclase (AC), whereas coupling with $G\alpha_i$ and $G\alpha_o$ suppresses AC activity. Coupling with $G\alpha_q$ activates phospholipase C, initiating phosphoinositide turnover and intracellular Ca^{2+} mobilization. Prediction of coupling specificity between GPCR and G protein subtypes has been attempted using precedent data from vertebrate GPCRs (Bourne, 1997; Wess, 1998; Horn *et al.*, 2000; Moller *et al.*, 2001). To what extent such methods are predictive for insect GPCR signaling remains an open question.

Numerous instances of Gβγ signaling also have been documented in the context of $G\alpha_{i/o}$ signaling. The target proteins for Gβγ include AC, PLCβ, potassium channels, and phosphatidylinositol 3-kinase. Perhaps the best known of these is K channel modulation following parasympathetic activation of heart muscarinic acetylcholine receptors to slow heartbeat frequency (Kofuji *et al.*, 1995). This response results from dissociation of $G\alpha_i$ and Gβγ, with the latter acting directly as a ligand to open G protein coupled inwardly rectifying potassium channels (GIRK) and hyperpolarize myocardial cells (Reuveny *et al.*, 1994; Wickman *et al.*, 1994). This signaling pathway provides a particularly clear example of how direct G protein modulation of ion channels leads to an important physiological response.

Analysis of the *Drosophila* genome sequence reveals seven, six, and two genes that are homologous to vertebrate Gα, Gβ, and Gγ subunits, respectively (**Table 4**). The seven Gα homologous genes are classified as $G\alpha_q$, $G\alpha_s$, and $G\alpha_{i/o}$, the latter including $G\alpha_t$, the well-known transducin involved in phototransduction (Simon *et al.*, 1991; Neves *et al.*, 2002) (**Figure 4**). Genes homologous to the Gβ subunit appear to have larger diversity than their vertebrate counterparts (**Figure 4**). Only two copies of the Gγ subunit are found in *Drosophila* (**Figure 4**). Alternatively spliced forms of these genes appear to provide additional flexibility to signaling systems (de Sousa *et al.*, 1989; Ray and Ganguly, 1994; Talluri *et al.*, 1995).

Immunolocalization of G protein α subunits in *Drosophila* demonstrated that expression of $G\alpha_q$, $G\alpha_s$, and $G\alpha_{i/o}$ is highly restricted in the CNS (Wolfgang *et al.*, 1990). Expression in photoreceptor synaptic terminals and antennal lobes suggests functional roles in transmission of primary sensory information. Distinct expression patterns in embryonic stages implies involvement of G protein-mediated sensory transmission in embryonic development (Wolfgang *et al.*, 1991). Expression profiles of Gα subtypes in *M. sexta* also were examined by immunohistochemistry, where they were shown to be expressed in subsets of CNS cells (Copenhaver *et al.*, 1995).

A salient characteristic of GPCR-induced signaling is the opportunity for amplification along multiple steps of the pathway. For example, a single GPCR binding event leads to dissociation of α and βγ subunits, each of which can trigger downstream signaling pathways. In instances where the G protein subunit triggers second messengers through activation of enzymes such as AC or PLC, a second level of amplification occurs. Downstream activation of additional enzymes such as kinases or phosphatases provides a third level of amplification. Thus activation of a very small number of GPCRs can elicit highly significant biochemical responses in target cells. The diversity of downstream signal transduction pathways is summarized in several reviews, and generalized current concepts based vertebrate studies may well be applicable to insects (Simon *et al.*, 1991; Morris and Malbon, 1999; Neves *et al.*, 2002).

5.5.6. Assignment of GPCR Functions

GPCRs regulate a plethora of cellular functions by modulating the activities of diverse intracellular

target proteins, including ion channels, metabolic enzymes, and transporters. These actions lead to cellular responses important for embryonic, postembryonic, and reproductive development, homeostatic processes, responses to environmental stimuli, and induction of various context-driven behavioral states.

Strategies for functional identification of GPCRs have gone through several phases since the initial breakthroughs with β-adrenergic and muscarinic acetylcholine receptors (Dixon *et al.*, 1986; Kubo *et al.*, 1986; Yarden *et al.*, 1986). These first discoveries began with direct protein purification and partial amino acid sequencing of receptors with known ligands. This allowed for construction of oligonucleotide probes, cDNA library screening, and eventual cloning and sequencing of entire receptors. The next wave of GPCR identification occurred through expression cloning of, among others, neurokinin2 and serotonin receptors using early stage oocytes of the African clawed toad, *Xenopus laevis* (Masu *et al.*, 1987; Julius *et al.*,

1988). Taking advantage of sequence information from earlier work, homology cloning based on nucleotide sequence identity provided relatively easy and productive approaches to further receptor identification. Such homology searches led to the identification of the first insect GPCR, the muscarinic acetylcholine receptor (Shapiro *et al.*, 1989). Finally, availability of entire genome sequences from an increasing number of organisms has led to an explosive phase of *in silico* discoveries of putative GPCRs (Kim and Carlson, 2002), while homology search using cDNA library screening and degenerate polymerase chain reaction (PCR) is still highly effective for GPCR identification in species for which whole genome sequences are not yet available.

Whereas early efforts focused on receptors with known function, the recent era of genome discovery has generated numerous "orphan receptors" with unknown ligands and uncertain functions. For example, large numbers of putative GPCR in insects have been identified and analyzed from the genome sequences of *Drosophila* and *Anopheles* (Hewes and Taghert, 2001; Hill *et al.*, 2002a). Homology analysis of putative *Drosophila* GPCRs and particularly for neuropeptide receptors (Hewes and Taghert, 2001) has provided a foundation for GPCR deorphaning based on comparisons with mammalian genomes. This analysis, combined with improvements in heterologous expression systems and reporter constructs, has increased the rate of GPCR deorphaning during the past several years.

Deorphaning putative GPCRs through identification of endogenous ligands depends primarily on heterologous expression within a suitable bioassay system, and characterization of interactions between candidate ligands through biochemical or functional methods. The choice of expression and assay systems for a given GPCR gene entail practical considerations based on knowledge of previous studies. Since the assay primarily focuses on ligand–receptor interaction rather than endogenous downstream pathways, it often uses an exogenously introduced reporter system. The most frequently used expression systems have been the *Xenopus* oocyte expression system and various cell lines. The expression system needs to be chosen according to certain criteria: paucity of receptor endogenous to the expression system, which might cross-react with ligands under investigation, robust expression of the heterologous receptor, localization of the receptor on the cell membrane, appropriate posttranslational processing, and efficient coupling to downstream signaling pathways for activation of reporters. **Tables 1–3** summarize assay systems currently used for studies of insect GPCRs.

5.5.6.1. Functional GPCR Assays: Coupling with Reporters

Given the diversity of functions regulated by GPCRs, it is not surprising that they are targeted by a high percentage of pharmaceutical drugs currently on the market. For this reason, considerable efforts have been devoted to development of methods for high-throughput screening of novel GPCR agonists and antagonists. It seems likely that similar approaches may lead to future insectidical agents.

The most straightforward functional assays for GPCRs in oocytes or cell lines register Ca^{2+} mobilization as an increased fluorescence or luminescence. This cellular response is most commonly a result of $G\alpha_q$ activation and phosphoinositol metabolism, leading to IP3 mediated Ca^{2+} release from intracellular stores (Neves *et al.*, 2002). Commonly used Ca^{2+} sensors generate fluorescence or luminescence signals (see Section 5.5.5.3). Many orphan GPCRs are coupled to other $G\alpha$ subunits that do not mobilize calcium. Consequently, efforts have been made to utilize more promiscuous G proteins coupled to the PLCβ pathway. One very successful method has been the use of a $G\alpha_q$ variant known as $G\alpha_{16}$, which couples widely divergent GPCRs to the phosphoinositide turnover pathway via PLC, leading to Ca^{2+} mobilization (review: Stables *et al.*, 1997; Kostenis, 2001) (**Figures 5 and 6**). For example, expression of a *Drosophila* odorant receptor with exogenous $G\alpha_{16}$ in *Xenopus* oocytes was the system used to identify its cognate odorant ligand (Wetzel *et al.*, 2001). Other approaches have involved engineering of chimeric G proteins (e.g., $G\alpha_{16/z}$) which couple a diversity of GPCRs to PLCβ (Liu *et al.*, 2003).

For fluorescence assays, cells expressing GPCRs are pretreated with membrane permeant calcium indicators such as Fura2-AM, fast green AM, or fluo-3 AM (Meeusen *et al.*, 2002; Choi *et al.*, 2003; Johnson *et al.*, 2003a). For luminescence responses in cells expressing aequorin, pretreatment with the cofactor coelenterazine is necessary. Fluorescence or luminescence microplate readers having injection ports can be used for introduction of the cells into microplate wells that contain various concentrations of ligand. For high-throughput assay, simultaneous injection and reading of a plate for 96 or 384 wells also has been developed (Le Poul *et al.*, 2002).

Coupling to G_s normally leads to increases in AC activity. Experiments with the *Xenopus* oocyte expression system have demonstrated that $G\alpha_s$ activation can gate exogenous inwardly rectifying potassium channels GIRK1 and GIRK2 through the direct action of $G\beta\gamma$ (Kofuji *et al.*, 1995; Lim *et al.*,

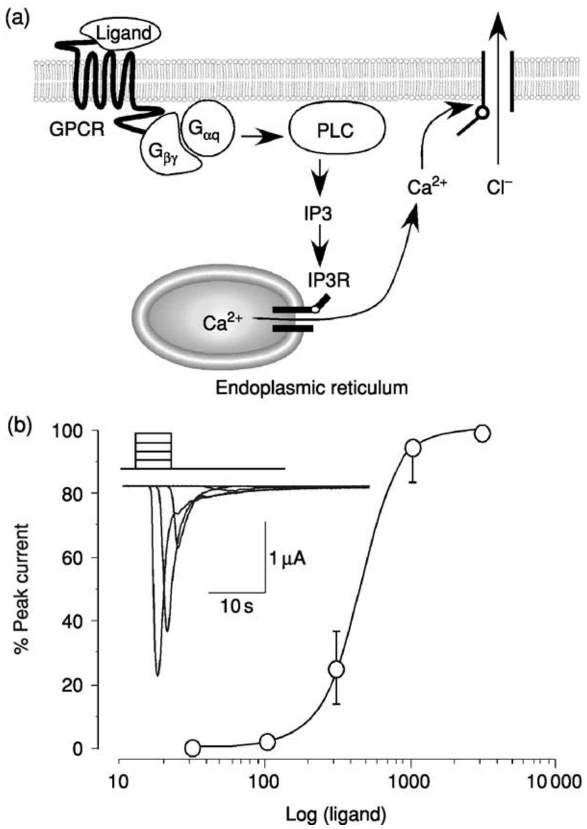

Figure 5 (a) A presumed signaling pathway in the *Xenopus* oocyte assay system for orphan GPCRs. GPCR expressed from injected cRNA transduce signal through phospholipase C (PLC), inositol triphosphate (IP3), and IP3 receptor triggering Ca^{2+} mobilization from intracellular Ca^{2+} storage. Ca^{+} activates chloride channels, resulting in inward currents. (b) Progressively higher concentrations of ligands generate larger currents. Mean values and corresponding standard deviations from multiple experiments are plotled as a function of ligand concentration.

1995; Peleg *et al.*, 2002). Expression of these exogenous GIRK subtypes in the proper stoichiometery can lead to robust inward K^+ currents, and hence provide a convenient assay for activation of $G\alpha_s$.

Other approaches for detecting $G\alpha_s$ activation have included measurements of increased cAMP levels (i.e., serotonin receptor 5HTR7) (Witz *et al.*, 1990; Saudou *et al.*, 1992; Obosi *et al.*, 1996). For $G\alpha_i$ activation, inhibition of AC activity can be detected through a reduction in forskolin-inducible cAMP increase (i.e., tyramine receptors) (Kutsukake *et al.*, 2000; Poels *et al.*, 2001).

5.5.6.2. Expression of GPCRs in *Xenopus* Oocytes

Advantages of using unfertilized *Xenopus* oocytes are many, not the least of which is the absence of endogenous GPCRs (Lee and Durieux, 1998). Injection of complementary RNA prepared with 5′ and 3′ untranslated regions of *Xenopus* β-globin gene results in sufficient expression in stage 5 or 6 oocytes for robust bioassays (Jespersen *et al.*, 2002). The oocyte contains sufficient machinery to link activation of exogenously introduced GPCRs to cellular responses.

The most routine use of oocytes is coupling of heterologously expressed GPCRs with endogenous G_q, leading to mobilization of intracellular Ca^{2+} through PLCβ activation and phosphoinositide turnover. This results in opening of Ca^{2+} dependent Cl^- channels on the oocyte plasma membrane and large inward currents that can be quantified by the two-electrode voltage clamp technique (**Figure 5**). This assay can be made considerably more flexible through the introduction of $G\alpha_{16}$, chimeric G proteins, or coupling to GIRK K^+ channels.

A precise perfusion system is required for generation of large sets of data using oocytes. Park *et al.* (2002) used a liquid chromatography pump and associated Rheodyne injection valve, supplying a continuous flow of buffer at a flow rate of $1.2\,\text{ml}\,\text{min}^{-1}$. Various concentrations of ligands were applied in standard 100 μl volumes of ligand through the injection valve, providing a 5 s exposure of ligand solution to the oocyte (Park *et al.*, 2002). This system allows precise application of a given concentration of ligand in a continuous flow of buffer, while caution must be exercised in the use of lipophilic ligands that may persist in the walls of the perfusion system even after extensive washes.

A challenge using *Xenopus* oocytes for GPCR assay is rapid desensitization following receptor activation. The degree of desensitization is highly variable and dependent on the specific GPCR expressed (Park *et al.*, 2002). In the case of *Drosophila* ETH receptors, the assay in oocytes was confounded by desensitization (Park, unpublished data). Even very low concentrations that did not elicit measurable currents were sufficient to cause desensitization. In such a case, alternative expression and assay systems using cell lines are preferable, where measurement of β-arrestin activity has proved to be a very effective method (see Section 5.5.6.4).

5.5.6.3. Assay of GPCR Activation in Cell Lines

Expression of GPCRs in cell lines currently is the method of choice both for deorphaning receptors and for large-scale, rapid-throughput drug screening for agonists and antagonists. Considerations in the choice of cell lines include high-level expression and proper processing of the exogenous GPCR gene, knowledge of the endogenous signaling systems operating, and the efficacy of the reporter system.

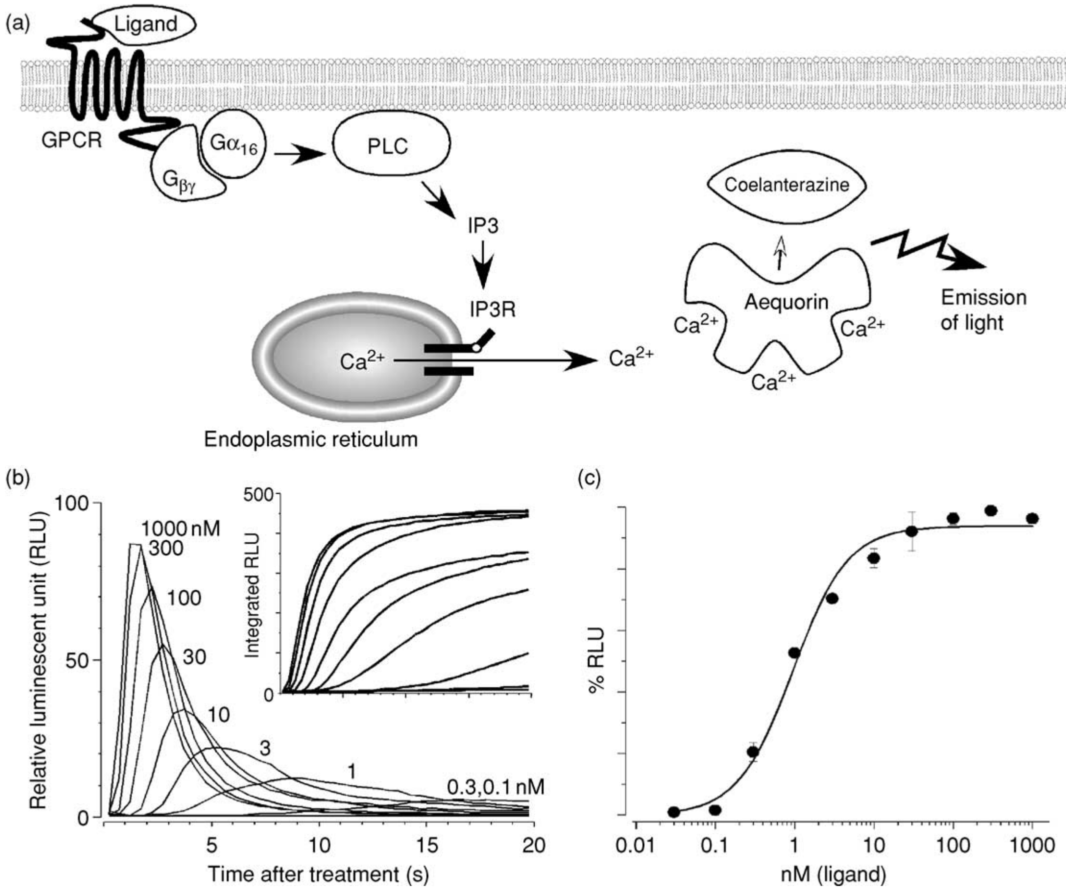

Figure 6 (a) A presumed signaling pathway operating in the aequorin assay for orphan GPCRs. The expressed heterologous GPCR transduces ligand binding through $G\alpha_{16}$, phospholipase C (PLC), inositol triphosphate (IP_3), and IP_3 receptor, resulting in Ca^{2+} mobilization from intracellular stores. Binding of Ca^{2+} to aequorin with the cofactor coelanterazine results in emission of light. (b) Progressively higher concentrations of ligand generate a more intense light response. (c) Integrated luminescence during a given time is used to generate the concentration–response curve.

Cell lines generally used for expression of insect GPCRs are Chinese hamster ovary (CHO-K1) cells, human embryonic kidney (HEK) cells, and Schneider's *Drosophila* (S2) cells (see **Tables 1 and 2**). All of these cells are known for their efficient coupling of GPCR activation to endogenous downstream signaling pathways. For instance, GPCRs expressed in CHO-K1 cells can be coupled to the PLC–calcium mobilization pathway, presumably via activation of G_q. A summary of downstream coupling mechanisms and signaling pathways for GPCRs in each cell line can be found at http://www.tumor-gene.org. Characteristics of *Drosophila* S2 cells are found in two recent publications (Van Poyer *et al.*, 2001; Torfs *et al.*, 2002b).

Both ligand binding assays and functional assays can be performed using cell line expression systems, depending on the need and situation. Affinity constants, receptor density, and kinetics of binding of heterologously expressed receptors can be investigated by using radioligands and compared with data obtained from native receptors (e.g., Johnson *et al.*, 2003b; Meeusen *et al.*, 2002). An advantage of the binding assay is that the biochemical properties of the expressed GPCR can be determined independent of coupling efficiency to downstream signaling and reporter activation.

5.5.6.4. Other GPCR Reporter Assays

While functional assays for GPCRs have been improved and refined through introduction of various reporter molecules into the expression system, rapid desensitization can severely attenuate responses. An effective strategy for dealing with this problem is to detect the interactions of β-arrestin with the GPCR. In this instance, desensitization of the GPCR can be monitored using bioluminescence resonance energy transfer (BRET). GPCR fused to *Renilla* luciferase is used for the cell line stably expressing arrestin fused to green fluorescent protein (GFP) (Barak *et al.*, 1997; Bertrand *et al.*, 2002). Activation of the GPCR leads to interaction between the

arrestin::GFP and GPCR::luciferase resulting in the BRET from the donor luciferase to the acceptor GFP. GPCR activation can be also measured by downstream gene regulation. Activation of GPCR coupled to AC and elevation of cAMP is monitored by expression of reporter gene controlled by cAMP responsive elements (CREs) (Chen *et al.*, 1995; Durocher *et al.*, 2000). It is thought that the CRE is activated though both $G\alpha_s$ and $G\alpha_q$ pathways (Durocher *et al.*, 2000). A simpler approach is to simply follow migration of a β-arrestin–GFP fusion protein to the cell membrane following GPCR activation (Barak *et al.*, 1997; Johnson *et al.*, 2003b).

The use of heterologous expression systems to obtain pharmacological profiles of GPCRs should be interpreted with appropriate caution, since it is often likely that critical transduction components unique to the natural physiological system will be absent. Thus the ligand affinities of certain GPCRs may be under the strong influence of native G protein subtypes with which they are associated (Kostenis, 2001). Even more complexity can be introduced in instances where relative stoichiometries of receptors to other cellular signaling components affect the assay system (Kenakin, 1997, 2003). Finally, the availability of specific G proteins appears to affect ligand binding affinity, as in the case of dopamine receptors (Reale *et al.*, 1997; Cordeaux and Hill, 2002; Gazi *et al.*, 2003).

5.5.6.5. Identifying Biological Functions of GPCRs

Understanding the biological function of a particular signaling pathway has been advanced through examination of ligand actions in large insects amenable to physiological experimentation. Important tools for endocrinological studies have been classical physiological experiments involving ligation, surgical extirpation and implantation of organs and tissues, parabiosis, and transplantations followed by bioassay-guided chemical isolation of the ligand on a particular system. Study of receptors mediating these processes provides further in-depth understanding of the mode of action of chemical signals at the molecular and cellular levels.

Biochemical and pharmacological data obtained through heterologous expression of a GPCR provides the first step in understanding molecular mechanisms of a signaling pathway and association of a putative authentic receptor with its ligand and physiological actions. Experimental evidence supporting an endogenous ligand–receptor interaction could include: highest affinity functional or biochemical interaction between the ligand and the receptor (usually at nanomolar to picomolar concentrations of ligand), spatial and temporal expression patterns of the GPCR that concurs with biological data, and mutant phenotypes that are in accordance with biological function of the signaling pathway.

Chemical isolation of unknown ligands for heterologously expressed orphan GPCRs is an increasingly useful method for functional analysis, especially with recently developed tools in proteomics. This approach is referred as reverse physiology (Birgul *et al.*, 1999) or reverse pharmacology (Civelli *et al.*, 2001) where the natural ligand for a receptor is sought. This approach contrasts with general approaches in which receptors are sought for a given ligand. Reverse physiology was successful in associating the peptide allatostatin A with its physiological receptor by isolating the peptide activating a *Drosophila* GPCR that is homologous to the somatostatin receptor of vertebrates (Birgul *et al.*, 1999). Three steps of peptide purification by cation-exchange column and reverse phase chromatography succeeded in isolation of a fraction active on the GPCR of interest. The final active fraction purified was analyzed by a matrix-assisted laser desorption ionization post source decay (MALDI-PSD) time-of flight spectrum for obtaining the sequence. A similar approach was successful for deorphaning *Drosophila* CG2114 as an FMRFamide receptor (Meeusen *et al.*, 2002).

Multidisciplinary approaches have been successful in a number of cases. Dow and his group studied signaling systems *Drosophila* Malpighian tubules mediating diuretic functions (review: Dow and Davies, 2003). Three neuroendocrine peptides and their signaling pathways implicated in the activation of fluid secretion were examined: cardioacceleratory peptide, diuretic hormone, and leucokinin. A combination of physiology, pharmacology, and *Drosophila* genetics elucidated downstream signaling pathways at the molecular and cellular levels. Specific GPCRs activated by leucokinin (CG10626) (Radford *et al.*, 2002) and cardioacceleratory peptide (CG14575) (Park *et al.*, 2002) were identified in functional assays. In the case of the leukokinin receptor, immunohistochemistry has been used to study its expression in stellate cells, a subtype of Malpighian tubule epithelial cell previously shown to respond to leucokinin by Ca^{2+} mobilization activating chloride current and fluid secretion (Rosay *et al.*, 1997; Radford *et al.*, 2002).

5.5.7. Conclusions

We find ourselves in an exciting era of exponential growth of knowledge regarding GPCR structure

and function. Knowledge of these receptors obtained in basic science could well to be applicable to the development of innovative pest control measures. Disruption of neuropeptide signaling systems through use of peptide hormone mimetics targeting the GPCRs also shows increasing promise (Nachman *et al.*, 2001, 2002a, 2002b). Chemical properties of pyrokinin analogs have been improved for increased cuticle penetrability and for resistance to peptidases (Nachman *et al.*, 2002a, 2000b). A novel method for delivering compounds to target GPCRs was attempted through use of a fusion protein combining lectin with allatostatin (Fitches *et al.*, 2002). By this means, allatostatin is delivered to insect hemolymph following oral ingestion and inhibits feeding and growth of the insect tomato moth (*Lacanobia oleracea*). With developing new biotechnology, GPCRs, particularly those mediating peptide signaling, may be excellent targets for pest control strategies providing an optimal range of specificity.

5.6 Scorpion Venoms

E Zlotkin, The Hebrew University of Jerusalem, Israel

5.6.1. A Chemical Ecology Perspective on Scorpion Venoms

Scorpions comprise an order of predatory, essentially nocturnal, venomous arachnids, which occupy temperate, desert, and tropical habitats. More than 1259 species of scorpion in 16 living families and 155 genera have been described (Fet *et al.*, 2000). The Buthidae family, with 48 genera and over 500 species, is the largest and most widespread of the scorpion families occupying all six faunal regions (Sissom, 1990). The buthids provide all the species that are dangerous to public health and are the most studied venoms; they include the insect selective neurotoxins, which are the main topic of interest in this article. This section deals with aspects in scorpion's biology related to their venom apparatus. Buthids, and other scorpions, employ their venom on two occasions. First, and most importantly, when they hunt and seize their prey and, second, when they are threatened. In both cases, scorpion stinging is an automatic response triggered by the reception of certain signals stimuli (see below).

5.6.1.1. Venoms

Venom is defined as a mixture of substances that is produced in specialized glands in the body of a venomous animal and introduced by the aid of a stinging-piercing apparatus into the body of its prey or opponent in order to immobilize/paralyze it. The vast majority of venomous animals (such as snakes, many spiders, certain marine snails, and various cnidarians) are slow, even static, predators that feed on freshly killed prey, which are comprised of mobile and relatively vigorous animals. Such a drastic difference in the locomotory capacity of the venomous predator compared to its potential prey demands special adaptations for prey encounter. These include behavioral adaptations in the form of ambush hunting tactics, and the development of the venomous apparatus. The latter allows for quick prey immobilization at the earliest possible moment in any encounter, with relatively low venom doses (see below). The goal of fast action at low doses is achieved with the aid of two devices. The first is a physical mechanical device, the stinging instrument,

which enables direct venom delivery into the prey's circulatory system, or in close proximity to the nervous and neuromuscular target tissues that control and operate the animal's locomotory system. The second is a chemical device in the form of the neuroactive constituents of the venom (neurotoxins).

For the present discussion, a neurotoxin is defined as a substance that affects the function of excitable tissues, due to specific recognition and binding affinity to given sites in these tissues. The various neurotoxins obtained from animal venoms are commonly classified according to their effects and sites of action in the nervous systems. They are thus defined as: ion channel toxins, which modify ion conductance; presynaptic toxins, which affect neurotransmitter release; and postsynaptic toxins, which interfere with the binding and the resulting effect on neurotransmitters (Zlotkin, 1987, 1991). A common characteristic of the various biologically active venom constituents, including neurotoxins, is their protein-polypeptide nature, which has dual significance. First, polypeptides, through their high diversity of covalent structures and the resulting spatial arrangements, may reveal a highly diverse array of functional specificities, such as a site directed highly selective neurotoxicity (see below). Second, polypeptides are the most available structures for modifications through evolutionary adaptations. Scorpions, as venomous organisms, provide a perfect example of the above principles (see below).

5.6.1.2. Scorpions

Scorpions, and their derived venoms, have attracted the attention of investigators mainly because of their hazard to human life and health. In nature, however, encounters between humans and scorpions are coincidental. The stinging activity of scorpions in the field is mainly directed towards arthropods, their prey/food (**Figure 1** and see below).

Figure 1 The yellow Israeli scorpion (*Leiurus quinquestriatus hebraeus*) attacking a large locust (*Locusta migratoria*). (Reproduced from Zlotkin, E., **1987**. Pharmacology of suvival: insect selective neurotoxins derived from scorpion venom. *Endeavour 11* (4), 168–174.)

Detailed coverage of the scorpion's biology, including its systematics, biogeography, life histories, feeding behavior, and prey encounters has been presented in previous and recent literature. Thus, the reader is urged to consult the following textbooks: *Venomous Invertebrates* (Bücherl, 1971); *Arthropod Venoms* (Bettini, 1978); *The Biology of Scorpions* (Polis, 1990a); and the most recent advanced study, *Scorpion Biology and Research* (Brownell and Polis, 2001). Several aspects related to venom delivery and employment deserve particular attention:

The sting. The scorpion body is divided into two major components, the cephalothorax and abdomen (opisthosoma). The abdomen is subdivided into a broad anterior preabdomen (mesosoma) and a narrow tail-like postabdomen (metasoma) (**Figure 1**). The latter consists of five segments plus the telson or "sting." The telson is subdivided into a bulbous vesicle and the needle-like oculeus (Levy and Amitai, 1980; Hjelle, 1990). The vesicle of the telson contains a pair of symmetrically localized venom glands. Each gland is provided with medial and dorsal compressor muscles that press the gland against the cuticle along its exterior lateral and ventral surfaces (**Figure 2**). The glands are separated by a median vertical muscular septum. Each gland is provided with an exit duct, which communicates to the exterior via two apertures just before the tip of the oculeus (**Figure 2**; Hjelle, 1990).

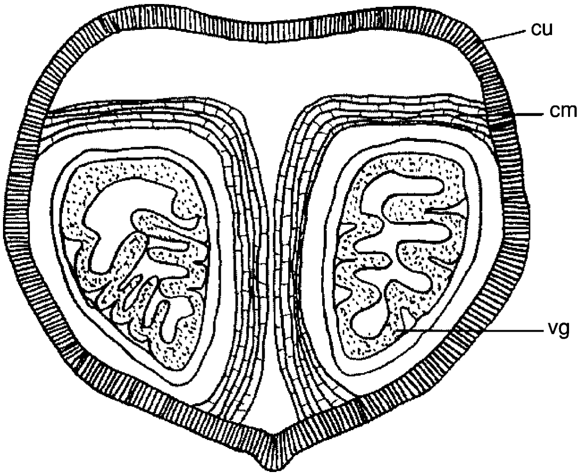

Figure 2 Diagrammatic representation of scorpion venom glands. cm, compressor muscles; cu, cuticle; vg, venom gland, showing secretory epithelial folding typical of the Buthidae. (Reproduced from Hjelle, J.T., **1990**. Anatomy and morphology. In: Polis, G. (Ed.), The Biology of Scorpions. Stanford University Press, pp. 9–63.)

Prey and predators. Scorpions are obligatory predators with a diverse diet composed mainly of insects and various arachnids, such as spiders, solifuges, and centipedes (McCormick and Polis, 1990). However, scorpions also eat crustaceans (isopods and gastropods) and occasionally vertebrates (small snakes, lizards, and rodents). Prey availability and abundance undergo seasonal changes (McCormick and Polis, 1990). Polis (1990) reported on 150 taxa of vertebrate and invertebrate organisms, which prey on scorpions, including birds, lizards, and insectivorous mammals. Certain Israeli fantoed geeko lizards, which prey on the extremely venomous yellow scorpion (*Leiurus quinquestriatus hebraeus*), were shown to possess a behavioral protection coupled with a physiological tolerance to the scorpion sting (Zlotkin *et al*., 2003). Thus, in addition to prey capture, the venom apparatus is also employed for deterrence of enemies. The existence of an aposematic coloration in animals, such as in scolopendrids and black widow spiders, may serve as a simple demonstration of its dual function. In nocturnal web or ambush (hidden) hunters, this aposematic coloration does not interfere with the predatory function of the venom apparatus.

Habitat plasticity. In contrast to the relative uniformity in their predatory feeding behavior, scorpions reveal a wide flexibility in their habitat diversity. Scorpions occupy diverse habitats including deserts, savanna, grasslands, temperate forests, tropical forests, rain forests, and intertidal zones, and snow covered mountains (Polis, 1990). Their habitat plasticity is exemplified by the distribution of *L. q. hebraeus* in Israel and the Sinai peninsula (Figure 3). These regions include heavily vegetated pockets of tropical climate (Tiberias lake and Jordan Valley), vegetated regions with a Mediterranean climate (Judean mountains), and extremely dry regions of Saharo-Sindic climate (central and southern Sinai). Similarly, this scorpion is found in various types of soils such as terra rossa, basalt, rendzina, loess, and stony desert (Levy and Amitai, 1980).

In desert habitats, scorpions appear to be one of the most successful and important predators in terms of density, diversity, biomass, and their role in community energetics and structure. The scorpions' success is attributed to their adaptability to extreme physical conditions (extreme cooling, immersion under water, high temperatures, extreme drought), their ability to conserve water, and an extremely low metabolic rate (the lowest for arthropods), which enable them to endure long periods of starvation (about a year) (McCormick and Polis, 1990; see Section 5.6.1.2.1). One of the strongest expressions of the ecological adaptability and success of scorpions is revealed by the chemical and pharmacological flexibility of their venoms.

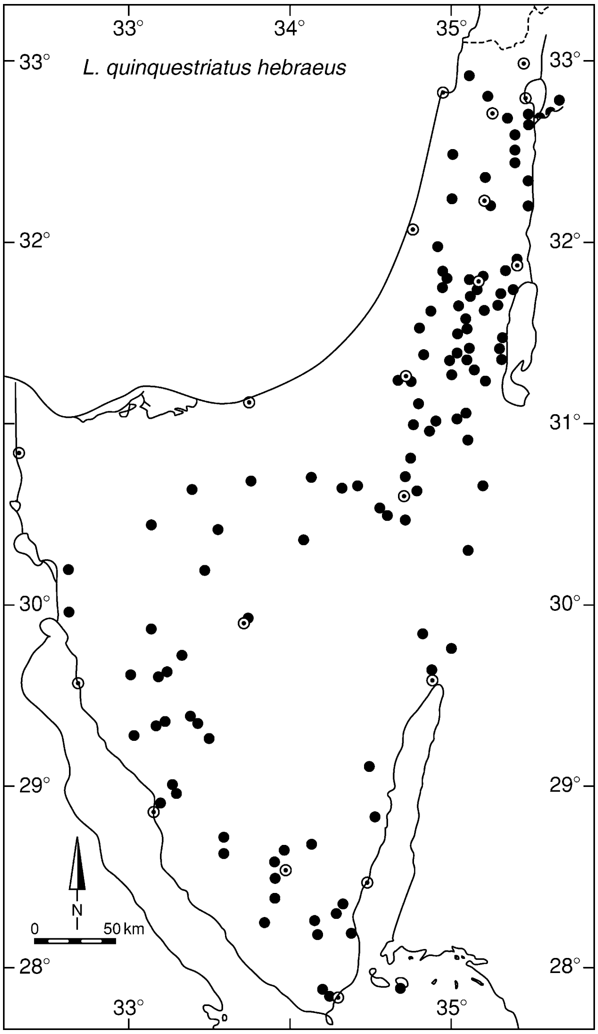

Figure 3 The distribution of the yellow Israeli scorpion (*Leiurus quinquestriatus hebraeus*, Buthidae) in Israel and Sinai. (Reproduced from Levy, G., Amitai, P., **1980**. Fauna Palestina: Scorpions. Magnes.)

5.6.1.2.1. Ambush hunters Foraging activity is reviewed by McCormick and Polis (1990). Briefly, foraging scorpions may either sit and wait or actively hunt prey. Active search for prey demands a comparatively greater expenditure of energy, and is, therefore, a less common foraging pattern. The majority are "sit and wait" ambush predators. For example, the sand scorpion (*Paruroctonus mesaensis* – see below) emerges from its burrow and remains motionless within a meter of the opening. Insects and other prey are detected (see below) as they pass close to the waiting scorpion. After

making contact with prey using its pedipalps a scorpion may or may not sting depending on the ratio of prey size to the predator's pedipalp size. Chelicerae initiate digestion by tearing the prey into smaller particles, which are collected in the preoral cavity.

McCormick and Polis (1990) stated that scorpions are able to consume large quantities of food at one time. Scorpions have an extremely low metabolic rate, much lower than that of insects. Various studies on insect metabolic rates (review: Keister and Buck, 1973) revealed an average value of 1000 mm O_2 $g^{-1}h^{-1}$ at 25 °C. Scorpions, however, have metabolic rates of 122.9 and 35.1 mm O_2 $g^{-1}h^{-1}$ for *Euscorpius* and *Nebo hierichonticus*, respectively (Dresco-Derouet, 1964a, 1964b). The above combination of consuming large quantities of food and low metabolic rates may explain the unusual capacity of the scorpion to survive starvation for 6–12 months or more (McCormick and Polis, 1990).

Most scorpions are opportunistic predators that accept most items of suitable size and physical-technical palatability. However, their preference for arthropods and insects is due to their availability. Therefore, small rodents and reptiles may occasionally be included in their menu. Detailed specification of scorpions' diet is described by McCormick and Polis (1990).

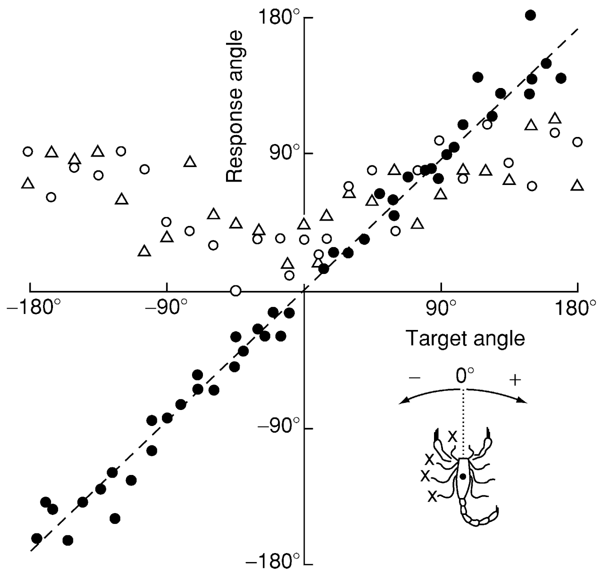

Figure 4 Directional orientation of *Paruroctonus mesaensis* to nearby disturbances of the sand. With eyes covered, *P. mesaensis* accurately turns to face the source of a substrate disturbance 8–10 cm away (filled circles). When the basitarsal slit sensilla are ablated unilaterally on all four legs, the angle of turning (open symbols) becomes biased in the direction of legs with sensors remaining intact. (+, –), Indicate right and left directions, respectively. (Reproduced from Brownell, P., Polis, G., **2001**. Scorpion Biology and Research. Oxford University Press, Oxford.)

5.6.1.2.2. Prey detection The precision in prey detection by scorpions as demonstrated by Brownell's extensive studies with the sand dune scorpion (*P. mesaensis*) is, presumably, achieved by many species (Brownell, 2001). Simple observations reveal that sand scorpions prey on insects and other small arthropods that crawl or fly towards the scorpion as it sits motionless (in ambush) outside the burrow. When a large insect such as cricket or burrowing cockroach moves within 20–30 cm of the hunting scorpion, it displays awareness of the prey by tensing its legs and opening its pedipalps. Prey movements trigger orientation responses of the scorpion, which rotates and moves forward to bring it 5–10 cm closer to the target (Brownell, 2001).

In summary, the sand scorpion is a nocturnal predator of small arthropods. Its prey detection is achieved not by vision or auditory stimulus, but rather by a mechanosensory organ. This latter organ is comprised of the ground-vibration sensitive' basitarsal slit sensilla and hairs of the tarsal leg segments, which perceive mechanical waves conducted through dry sand. The role of the basitarsal slit sensilla, in directional orientation of the sand scorpion, is exemplified in Figure 4. At close distances the *trichobotria* hairs on the pedipalps detect air currents induced by prey movements, and these guide the prey capturing appendages to the target. Finally, it may be noted that sensory behavioral prey detection is aimed at identifying the size and direction of the prey (Brownell, 2001). The hairs do not distinguish between phyletic categories of prey organisms. Such distinction, however, can be provided by the specific pharmacology of scorpion venom components.

5.6.1.3. Regulated Venom Secretion

5.6.1.3.1. Collection Scorpion venom is commonly collected by the aid of rapid, time-saving, "electrical milking," where venom is forcibly released by an electrical stimulation of the telson. A scorpion can also be induced to spontaneously release venom by mechanical stimulation of its telson (manual venom) (el Ayeb and Rochat, 1985; Martin *et al.*, 1987). A more convenient method to obtain a natural venom is by inducing a scorpion to sting a hydrophobic parafilm membrane, from which the deposited natural venom can be easily collected by a callibrated glass capillary (Zlotkin and Shulov, 1969; Zlotkin and Gordon, 1985).

5.6.1.3.2. Diversified venom composition Scorpion venom is substantially composed of components of unknown biological activity, such as the

nonsoluble acidic mucoproteins, nucleotides, and various low molecular weight salts and organic substances (Simard and Watt, 1990). Low levels of non-neurotoxic enzymatic activity have been detected occasionally, such as phosphatase, hyaluronidase (spreading factor), or phospholipase (Simard and Watt, 1990). However, the lethal and paralytic toxicities and pathogenicity of scorpion venom are derived from low molecular weight, single chain basic polypeptides, which specifically affect ion conductance in excitable tissues (see below).

When different samples of either pooled or individually collected venom derived from scorpions belonging to the same species were compared, chemically or immunologically, obvious differences in composition were revealed among geographically separated scorpions (el Ayeb and Rochat, 1985) as well as different methods of venom collection (el Ayeb and Rochat, 1985; Martin *et al*., 1987). Also, a careful analysis of scorpion venom derived from natural stings has revealed a curious variability among venom samples collected from successive stings of individual scorpions (Yahel-Niv and Zlotkin, 1979; Inceoglu *et al*., 2003). The above variability, however, displays an consistent pattern (see below).

5.6.1.3.3. Naturally secreted venom The employment of the device used for the collection of scorpion venom immediately after being released by natural stings (Zlotkin and Shulov, 1969) facilitated the analysis of successive venom drops deposited by continuous stinging from individual *L. q. hebraeus* scorpions. The authentic natural venom was examined for its appearance, protein content, electrophoretic mobility, and paralytic activity to blowfly larvae. It was shown that venom obtained by a series of successive stings changes its appearance in the following order: transparent, opalescent, and viscous secretions. As shown in Table 1, venom collected from individual scorpions demonstrates a wide variability in the number of venom-yielding stings, volume of secreted venom, protein content, and total and specific toxicities. The opalescent venom secretion exhibited the highest total and specific toxicities, in contrast to the transparent venom, which possessed the lowest toxicity. Electropherograms of opalescent and viscous venom secretions closely resemble each other, and both differ from the transparent venom, which had fewer protein bands and lower toxicity (Yahel-Niv and Zlotkin, 1979). A similar diversity in the composition of the successively secreted

Table 1 The diversity in the properties of *L. quinquestriatus hebraeus* venom obtained from individual scorpions by natural stings

Property	*Range*[a]	*Average ± SD*[a]
Venom yielding stings (number)		
Total venom	37–93	65 ± 16
Transparent venom	13–47	27 ± 12
Opalescent venom	6–24	13 ± 5
Viscous venom	8–38	24 ± 11
Volume (μl)		
Total venom	18.5–52	36 ± 11
Transparent venom	5.5–14	8.2 ± 2.4
Opalescent venom	6.0–16	10.8 ± 3.7
Viscous venom	6.5–29	16.5 ± 7.6
Protein content[b]		
Total venom (μg)	1 920–6 490	3 689 ± 1 387
Transparent venom concentration ($\mu g\,\mu l^{-1}$)	90–160	115 ± 33.4
Opalescent venom concentration ($\mu g\,\mu l^{-1}$)	70–180	129 ± 33.7
Viscous venom concentration ($\mu g\,\mu l^{-1}$)	40–200	81 ± 48.0
Specific toxicity (CPU mg^{-1})[c]		
Transparent venom	450–33 300	7 300 ± 14 000
Opalescent venom	930–100 000	27 000 ± 21 200
Viscous venom	1 430–50 000	14 300 ± 17 000
Total toxicity (CPU)[c]		
Transparent venom	500–4 330	1 200 ± 1 500
Opalescent venom	960–52 000	25 900 ± 23 000
Viscous venom	1 100–30 330	9 700 ± 17 400

[a] Ranges, averages, and standard deviations were based on 10 determinations each.

venom has been recently demonstrated in the venom of the South African scorpion *Parabuthus transvaalicus* (Buthidae) (Inceoglu *et al*., 2003) with far-reaching pharmacological implications. As with the *Leiurus*, the *Parabuthus* scorpion, when stimulated to sting, first secretes a transparent venom (the prevenom) followed by an opaque (cloudy dense) secretion named venom. Similar to the transparent venom of *Leiurus*, the prevenom of *Parabuthus* comprises a relatively small fraction of the volume (22% and 5%, respectively) and of the total protein (25% and 10%, respectively). However, beyond the above similarity, the *Parabuthus* prevenom reveals a qualitative-fundamental difference. In contrast to the *Leiurus* transparent venom which possesses only about 3–4% of total toxicity with four times lower specific toxicity than the opaque venom (Table 1), the prevenom of *Parabuthus* possesses a higher specific toxicity. This toxicity includes higher insect paralysis (×3), mouse lethality (×1.2), and pain production (×3.5) when compared to the dense cloudy venom (Table 2). The potent toxicity of the prevenom is surprising in view of the data presented in Figure 5, showing that it is devoid of the 6–7 kDa long chain polypeptides, which include the potent insect and mammalian neurotoxic

Table 2 Comparative properties of prevenom and venom of *Parabuthus transvaalicus*

	Prevenom	*Venom*
Protein (mg ml^{-1}, $n = 8$)	7.2–14.3	53.4–85.2
Potassium salt (mM)	80.2 ± 4.5	5.4 ± 0.4

μl venom/20 g mouse	0.5	0.1
Pain response (foot licking for 10 min after injection)	32 ± 2.6	9.3 ± 2.0

Reproduced with permission from Inceoglu, B., Lango, J., Jing, J., Chen, L., Doymaz, F., *et al*., **2003**. One scorpion, two venoms: prevenom of *Parabuthus transvoalicus* acts as an alternative type of venom with distinct mechanism of action. *Proc. Natl Acad. Sci. USA 100* (3), 922–927.

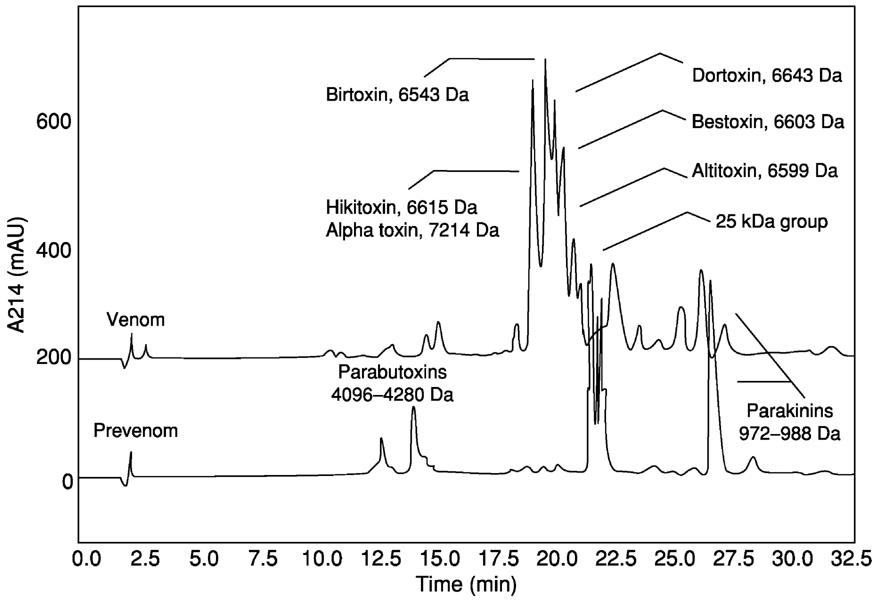

Figure 5 RP-HPLC profiles of prevenom and venom from *Parabuthus transvaalicus*. The venoms are ran on a C8 microbore analytical column and the absorbance at 214 nm is monitored and components are identified by online mass spectrometry (LC-MS). Both prevenom and venom contain the 0.9–1.2 kDa group, the 3–4 kDa polypeptide group, and the 25 kDa group. However, most of the protein in venom corresponds to the 6–7 kDa peptide group. Moreover, the three protein groups in prevenom are major species because of the lack of the 6–7 kDa group. (Reproduced from Inceoglu, B., Lango, J., Jing, J., Chen, L., Doymaz, F., *et al*., **2003**. One scorpion, two venoms: prevenom of *Parabuthus transvaalicus* acts as an alternative type of venom with distinct mechanism of action. *Proc. Natl Acad. Sci. USA 100* (3), 922–927.)

polypeptides that affect the voltage-gated sodium channels (see Sections 5.6.2 and 5.6.3). The pharmacologic uniqueness of the prevenom is attributed (Inceoglu *et al.*, 2003) to the presence of a high concentration (80 mM) of K^+ salt and certain peptides (**Figure 5**) that block the voltage-gated rectifying K^+ channels. The combined action of these two factors causes a strong local and prolonged depolarization that blocks neuronal conduction and induces pain. Therefore, it appears that the depolarizing effect of high extracellular K^+ provided by the prevenom, serves as a pharmacological substitute to the long chain sodium channel gating modifiers. Therefore, it is claimed that by virtue of its unique composition the prevenom economizes the metabolically expensive polypeptides, positively cooperates with the opaque venom, and fulfills an important defensive role as a pain producer (Inceoglu *et al.*, 2003).

It may be concluded that prevenom functions as a separate chemical and functional entity (one scorpion two venoms). This concept challenges the "pharmacological monopoly" of neurotoxic polypeptides and provides an efficient alternative solution to their insecticidal action (Inceoglu *et al.*, 2003). Thus, the transparent venom of *Leiurus*, due to its low and marginal toxicity, is not equivalent to the prevenom of *Parabuthus*. It may, however, fulfill a synergistic role with the opaque venom deserving experimental clarification. In contrast to the *Parabuthus* prevenom, the low toxicity of the first secreted transparent *Leiurus* venom contradicts the fundamental needs of the slow predator, which has to paralyze its mobile prey in the fastest possible manner. Alternatively, it provides a rational explanation for the phenomenon of multiple stinging of a mobile and vigorous prey, such as the migratory locust (Zlotkin, 1987). In other words, the process of stinging begins with a metabolically cheap venom and continues with a more potent ("expensive") venom when needed.

The phenomenon of the *Leiurus* transparent venom is very reminiscent of the observation of Bücherl (1955) who found that drops of electrically milked venom of *Tityus serrulatus* and *T. bahiensis* become successively more opalescent and viscous and more toxic to mice. Alternatively, the *Parabuthus* prevenom phenomenon is supported by an early observation (Miranda *et al.*, 1964), which indicated that the specific toxicity (by weight) of the "manual venom" (see above) was about four times that of the electrically obtained venom.

Finally, given the background of the above-mentioned variability in the successively secreted scorpion venom, it appears that scorpion venom production and secretion is a regulated timed process, enabling precise control of the prey's response and behavior. Such a goal may be achieved, for example, by the preprogramed secretion of insect selective neurotoxins (see Section 5.6.3.2.5).

5.6.1.4. Phyletic Specificity

5.6.1.4.1. An ecological point of view Organisms show a range of tolerance to various environmental factors. Ecologists use the prefixes "steno" and "eury" to refer to organisms with a narrow and wide, respectively, range of tolerance to a given factor. Thus, a stenothermic organism will tolerate only narrow variations in the ambient temperature. For example, the cold adapted antartic fish, *Trematomus bernacchi*, tolerates temperatures between −2 °C and +2 °C only. In other words, a steno type tolerance is exhibited by an organism that has acquired an adaptation to a strictly stable environment. The scorpions, as demonstrated by their geographical distribution, exhibit a *eury* type of tolerance to factors such as temperature, light, and humidity. However, they have strict requirements for prey organisms, which substantially consist of small arthropods and soft bodied insects. This steno type of feeding provides the necessary prerequisite for a chemical-pharmacological adaptation to the strict food supply.

5.6.1.4.2. Animal group specificity Animal group specificity refers to the phenomenon where animal venom and/or its derived toxins reveal toxicity to a given group of organisms, but are not effective against other organisms. For example, the venoms of marine nemertine worms (Rhynchoceola) and sea anemones (Cnidaria) are capable of affecting a wide range of animals, but their toxicity to crustacea is due, substantially, to a specific group of polypeptide neurotoxins (molecular weight (M_r) 3–6 kDa) that do not affect vertebrate and other invertebrate animals (Kem, 1976; Schweitz *et al.*, 1981). In cases where a venomous organism feeds on a given and limited group of animals, the phyletic specificity is manifested at the level of the whole venom. For example, the venomous marine Conidae snails are subdivided according to their feeding habits into fish, mollusk, and worm eaters. A series of early bioassays (Endean and Rudkin, 1963, 1965) revealed that the above feeding preference is associated with the specific toxicity of their venoms, which are aimed at the respective groups of prey animals. Moreover, this notion of animal group selectivity was demonstrated in the form of mollusk selective δ-conotoxins, which slow inactivation exclusively in the mollusk voltage-gated sodium channels (VGSCs) (Fainzilber

et al., 1994), or the insect selective ω-atracotoxins derived from Australian funnel web spiders that selectively block the insect voltage-gated calcium channels (Fletcher *et al.*, 1997; Wang *et al.*, 1999).

This phenomenon of animal group selective neurotoxins represents a chemical adaptation of the venom to the animal's specific prey or, more precisely, to certain peculiarities in the structure and function of the prey's nervous system. These animal group selective toxins indicate the occurrence of subtypes of voltage-gated channels specific to given groups of organisms (Zlotkin, 1991; see below).

5.6.1.4.3. Ion channel subtypes As a key structure of excitability (see Section 5.6.4.3.1) in biological systems, the VGSC is targeted by many toxicants (**Table 3**) derived from plant and animal systems (Catterall, 1980; Cestele and Catterall, 2000), as well as various synthetic pesticides (**Table 3**) (Soderlund and Knipple, 1995; Zlotkin, 1999). These toxicants interfere with all three fundamental functions of the VGSC, namely its selective ion transport (groups 1 and 9), voltage dependent initial increase in permeability (activation, groups 2, 4, 5), and the subsequent voltage dependent return to the resting sodium permeability (inactivation, groups 3, 6, 7, 8). The scorpion venom neurotoxins are represented in **Table 3** by the beta toxins (site 4 activation enhancers) and alpha toxins (site 3, which substantially inhibit inactivation) (Soderlund and Knipple, 1995; Gordon, 1997b; Section 5.6.2).

Sodium channel neurotoxins that are transport inhibitors or are gating (activation/inactivation) modifiers share two important features. First, they differentiate between the three distinct functional states (resting, open, inactivated) of the channel, and show an increased affinity to the specific conformation of a given state. Second, the various site groups of bound toxins interact with one another through an allosteric interaction or coupling (**Table 3**). This aspect of cooperativity may have far-reaching practical agronomical implications (Section 5.6.5.2).

Table 3 Neurotoxin and insecticide binding sites on the voltage-gated sodium channel

Site[a]	*Toxicant*[b]	*Physiological effect*	*Allosteric coupling*[c]
1	Tetrodotoxin (TTX) Saxitoxin (STX) μ-Conotoxin	Inhibit transport	+3, 5, −2
2	Barachotoxin (BTX) Veratridine Aconitine Grayanotoxin *N*-Alkylamides	Cause persistent activation	+3, −6
3	α-Scorpion toxins Sea anemone II toxin (ATXII)	Inhibit inactivation Enhances persistent activation	+2
4	β-Scorpion toxins	Shift voltage dependence of activation	
5	Brevetoxins Ciguatoxins	Shift voltage dependence of activation	+2, 4, −3
6	δ-Conotoxins (δ-TxVIA)	Inhibit inactivation	
7	DDT and analogs Pyrethroids	Inhibit inactivation[d] Shift voltage dependence and rate of activation	+2, 3, 5
8	*Goniopora* coral toxin *Conus striatus* toxin	Inhibit inactivation	
9	Local anesthetics Anticonvulsant Dihydropyrazoles	Inhibit transport	+2

[a]Sites 1–5 according to Catterall (1992), site 6 according to Fainzilber *et al.* (1994), site 7 according to Pauron *et al.* (1989) and Soderlund and Knipple (1995). Sites 8 and 9 were numbered arbitrarily in order to distinguish them from the others. Site 9 according to Soderlund and Knipple (1995) and Payne-Gregory *et al.* (1998). Substances are considered to belong to a given site if they compete with each other in binding assays and induce similar electrophysiological effects.
[b]Toxins and insecticides.
[c]Allosteric coupling refers to modulations induced by occupancy of a receptor site by the corresponding neurotoxin on the binding of neurotoxins at the indicated receptor site(s). Positive modulation (+) indicates enhancement of binding of the toxin at its indicated receptor site and/or stimulation of Na^+ influx. Negative modulation (−) refers to decrease in toxin binding at the indicated receptor site (Gordon, 1997a).
[d]See Soderlund and Knipple (1995).
Reproduced with permission from Zlotkin, E., **1999**. The insect voltage-gated sodium channel as target of insecticides. *Annu. Rev. Entomol. 44,* 429–455.

An additional feature of the pharmacological diversity of the VGSCs is revealed by the ability of different toxicants to identify minor differences in ion channel subtypes. For example, neurotoxic conotoxins, derived from the fish hunting *Conus geographus* snail, are able to distinguish among certain categories of voltage-gated calcium and sodium channels (Zlotkin, 1991). Similarly, as discussed in Section 5.6.3.3.2, the alpha scorpion toxins can be separated into several categories each representing a binding preference to a distinct subtype of the voltage-gated sodium channels. The first indication of channel subtypes that can be distinguished by neurotoxins was demonstrated by the animal group (phyletic) selectivity of scorpion venom neurotoxins (Zlotkin *et al.*, 2000). The insect selective neurotoxin AaIT (see below), derived from the venom of the North African scorpion *Androctonus australis* Hector, provided the first example of an animal group specific toxin (Zlotkin *et al.*, 1971c). As shown below, this finding has led to certain practical agronomical applications (see Section 5.6.5).

5.6.1.4.4. Factors specific to arthropods The symptoms of scorpion envenomation in arthropods mainly indicate a stimulatory effect on the skeletal musculature (Rathmayer *et al.*, 1978), which, in blowfly larvae, is expressed as an immediate and sustained contraction of body muscles accompanied by a complete paralysis (**Figure 6a**). The degree and duration of paralysis are dose dependent (Zlotkin *et al.*, 1971a). This paralysis of blowfly larvae was hence employed as a quick, specific, and sensitive bioassay for the evaluation of the potency of scorpion venoms, and for the detection and monitoring of AaIT toxin purification (see below).

There is an apparent resemblance between the effects of scorpion venoms on arthropods and on mammals, as observed by the similarity in action of scorpion venom on neuromuscular preparations derived from insects, crustaceans (Parnas and Russel, 1967; Parnas *et al.*, 1970), and mammals (Katz and Edwards, 1972; Brazil *et al.*, 1973; Zlotkin *et al.*, 1978). In all these preparations, the scorpion venom stimulates skeletal muscles due to its presynaptic excitation of exposed motor nerve endings, resulting in the release of the corresponding transmitter. This similarity in action could have led to the conclusion that the effect of scorpion venoms on mammals and arthropods was due to the same chemical factors in crude venoms.

However, using the blowfly larvae assay (**Figure 6**), Zlotkin *et al.* (1971a) showed that there was no correlation between larval paralysis and mice lethal potencies for 16 different Buthidae venoms, suggesting that the two toxic activities may result from different factors. These results were supported by the finding that the AaHI and AaHII toxins, which were strongly lethal to mammals and isolated according to their toxicity to mice (Rochat *et al.*, 1967; Miranda *et al.*, 1970), were inactive against blowfly larvae (Zlotkin *et al.*, 1971). Final proof of toxin diversity between those affecting mammals and those paralyzing insects was obtained by starch-gel-electrophoretic separation of the venom of *A. australis* and six other Buthidae scorpions. Three of these venoms contained more than one fraction that caused larval paralysis. These fractions were lethal to fly larvae, and were readily inactivated by trypsin, thus demonstrating their protein nature (Zlotkin *et al.*, 1972b).

These early findings led to the detection and isolation of AaIT (see below) and other insect selective neurotoxins. The existence of an additional group of toxins, the crustacean toxins, was initially demonstrated by the fact that, in contrast to the crude venom of *A. australis*, both the insect selective AaIT and the highly mammalian toxic AaHII, were unable to affect an isopod (terrestrial crustacean) or another scorpion (**Table 4**). These data suggested the presence of discrete neurotoxins (Zlotkin *et al.*, 1972a, 1975) specifically affecting those arthropods. Using a bioassay of isopod paralysis, coupled with gel filtration and ion exchange column chromatography, a protein specifically toxic to isopods (crustacean toxin, AaCT) was isolated and purified from the venom of *A. australis* (Zlotkin *et al.*, 1975). Several crustacean toxins have also been isolated from the venom of scorpionid scorpion *Scorpio maurus palmatus* (Lazarovici *et al.*, 1984) and certain South American scorpions (Possani *et al.*, 1999, 2000).

As shown in **Table 5**, the animal group specificity of various neurotoxins, in addition to the conventional toxicity assay with intact animals (**Table 4**), was also demonstrated on neuromuscular preparations from mammal, insect, crustacean, and arachnid. The crustacean toxin has the highest specific toxicity to the crustacean and arachnid neuromuscular junctions. In other words, from a chemical ecology point of view, the presence of animal group specific toxins (antimammals, anti-insects, anticrustaceans), in the venom of *A. australis*, represents a specific pharmacological adaptation to the four major classes of scorpion prey or enemy organisms, namely, the insects, arachnids, isopods, and vertebrates.

Finally, it is noteworthy that this concept of insect selectivity has been well accepted. In recent years, hundreds of publications have reported

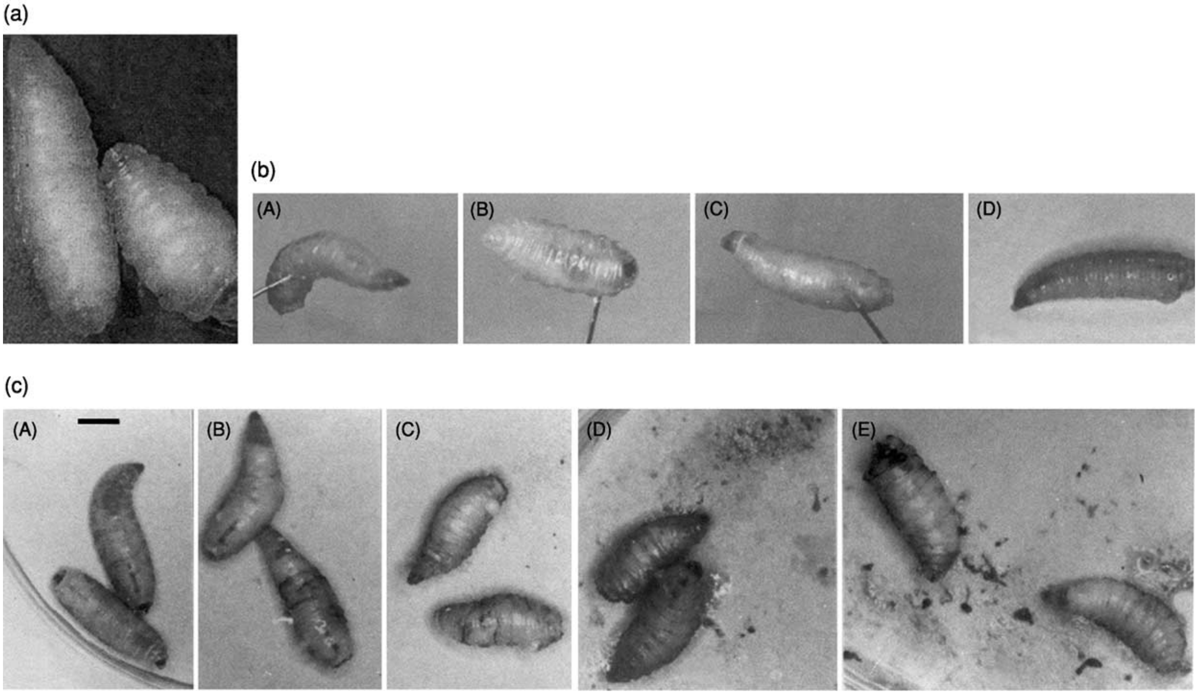

Figure 6 The response of *Sarcophaga falculata* blowfly larvae to the insect specific toxins derived from Buthidae scorpions, affecting voltage-gated sodium channels (VGSCs). The larvae (100–120 mg of body weight) are injected with 2–5 μl of saline solution containing the test substance into the ventral hind part of the body cavity. (a) Shows the fast contraction paralysis induced by the excitatory toxins. The contracted larva (right) was photographed about 5 s after injection compared with a saline injected larva (left). (b) Typical response of a larva injected with one paralytic unit (50 ng) of the depressant LqhIT2 toxin: (A) the larva mounted on the needle connected to a Hamilton syringe is wiggling; (B) 5–10 s after injection the larva reveals a transient fast contraction of 2–3 s duration, followed by the development of progressive flaccidity; (C) the larva 60 s after injection reveals the flaccid extended paralysis; and (D) 5 min after injection it is completely motionless with an extended body. (c) Demonstrates the delayed extended contraction paralysis induced by injection of 1 paralytic unit (30 ng) of an α type toxin (LqhαIT) to two larvae: (A) before injection (scale bar = 2.5 mm); (B) 1 min after injection – mobile and without detectable change in body form; (C) 5 min – obvious contraction and immobility; (D) 8 min – fully contracted and paralyzed. The contraction causes release of hemolymph from the injection site. The hemolymph darkens upon exposure to air; and (E) 20 min – still contracted but with partial recovery of mobility. The above responses were used as assays to monitor the isolation of the above toxins by column chromatography. (According to Zlotkin, E., Eitan, M., Bindokas, V.P., Adams, M.E., Moyer, M., *et al.*, **1991**. Functional duality and structural uniqueness of depressant insect-selective neurotoxins. *Biochemistry 30* (19), 4814–4821; and Eitan, M., Fowler, E., Herrmann, R., Duval, A., Pelhate, M., *et al.*, **1990**. A scorpion venom neurotoxin paralytic to insects that affects sodium current inactivation: purification, primary structure, and mode of action. *Biochemistry 29* (25), 5941–5947.)

the characterization of additional insect selective scorpion toxins (Possani *et al.*, 2000).

5.6.2. The Vertebrate Affecting α and β Toxins

This article is motivated and directed by entomological–chemoecological considerations. However, like any other aspects of toxinology, early studies of scorpion venoms were pursued for clinical and public health purposes, using vertebrates as test animals and experimental systems. Thus, the present section provides a short overview on the “classical” chemistry and pharmacology of scorpion venom, to serve as a background for the entomological aspects that follow. The reader is invited to consult some early (Zlotkin *et al.*, 1978; Rochat *et al.*, 1979; Possani, 1984) and more recent (Simard and Watt, 1990; Martin-Eauclaire and Couraud, 1995; Loret and Hammock, 2001) review articles for more detailed information.

5.6.2.1. The Buthid Envenomation Syndrome

The clinical and public health aspects of scorpion stings can be summarized by the following statements:

1. Fewer than 25 species of scorpions, belonging to eight genera, are lethal to humans and all belong to the family Buthidae.

Table 4 The selective toxicity of AaIT and AaHII toxins

Test animal	A. australis *crude venom*	*AaHII*	*AaIT*
Flies, adults (*Sarcophaga*)	+	−[a]	+
Beetle, adults (*Tenebrio*)	+	−[a]	+
Beetle, larvae (*Tenebrio*)	+	−[a]	+
Cockroaches, adults (*Periplaneta, Blatella)*	+	−[a]	+
Locusts, adults, larvae (*Locusta)*	+	−[a]	+
Crickets, adults, larvae (*Gryllus*, *Acheta*)	+	−[a]	+
Arachnids (*Buthus*, scorpions)	+	−[a]	−[a]
Crustaceans (*Armadillidium*, Isopods)	+	−[a]	−[a]
Laboratory mice	+	+	−[a]

[a]The toxins were injected in doses that were at least 20 times higher than their equivalent active doses of the crude venom as estimated on the basis of their purification yields.

Reproduced with permission from Zlotkin, E., **1986**. The interaction of insect selective neurotoxins from scorpion venoms with insect neuronal membranes. 2. The public health hazard is declining due to recent progress in the availability of medical services. Scorpion stings, however, continue to account for hundreds of death worldwide each year. Morbidity and mortality are higher in children.
3. Scorpion neurotoxins induce local and systemic effects expressed in severe cardiovascular, respiratory, and muscular manifestations that precede death. The latter may occur within a few hours after envenomation.
4. Serotherapy, coupled to symptom directed drugs, can prevent lethality.
5. The toxicity of scorpion venom to humans is attributed to low molecular weight (4–8 kDa) basic polypeptides, which affect various ion channels in excitable membranes.
6. Envenomation in humans has three major symptoms: (a) muscular effects, in the form of contraction, twitchings, and fibrillations, are the most common abnormalities; (b) cardiovascular effects, such as electrocardiographic abnormalities, hypertension, and pulmonary edema, being the most dangerous; and (c) respiratory effects revealed by typical irregularities of respiratory movements (“Chayne Stokes” type), including respiratory paralysis, often occur.
7. All the above manifestations are a consequence of either an indirect effect, mediated by the nervous tissue innervating the target organs (heart, blood vessels, muscles), or a direct effect, mediated by the heart, skeletal, and smooth muscles related to the target organs.

8. The fact that a scorpion sting can kill or even affect a human being is astonishing, considering the small amount of venom injected. Yahel-Niv and Zlotkin (1979) evaluated that an average sting of *L. q. hebraeus* has a volume of 0.55 µl, which includes 57 µg of protein. Similar data were reported by Rochat *et al.* (1979) for the deadly North African scorpion, *A. australis* Hector, which injects only 100–200 µg (dry weight) of the whole venom, of which only 5% comprises active neurotoxins.
9. Both indirect and direct effects are produced by the same fundamental mechanisms, namely, an action on the VGSCs by the so-called α or β neurotoxins (see Section 5.6.2.2) present in the venom.

5.6.2.2. Toxins Affecting the Vertebrate VGSCs

Scorpion neurotoxins that affect the vertebrate VGSCs are subdivided into two categories, the α and β toxins. Both are long chain scorpion toxins (60–70 amino acids, four disulfide bridges) (Loret and Hammock, 2001), similar to the insect selective neurotoxins (see Sections 5.6.3 and 5.6.4).

5.6.2.2.1. Alpha toxins These were the first buthid scorpion toxins studied. They mimic and reproduce the effect and symptoms of the crude venoms to vertebrates (Miranda *et al.*, 1970). The α toxins are characteristic of "old world" Afro-Asian buthid scorpions. Some α toxins, however, were found in the venom of the South American *Tityus* and *Centruroides* scorpions (Barhanin *et al.*, 1982; Meves *et al.*, 1984). The scorpion α toxins are the most studied group in toxinology (see the above review articles), as they:

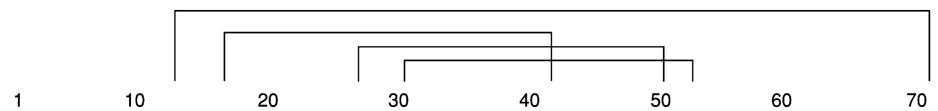
1. prolong action potentials due to the slowing of sodium channel inactivation (Adam *et al.*, 1966; Wang and Strichartz, 1983; Benoit and Dubois, 1987);
2. synergize interaction with lipophilic alkaloidal sodium channel activators (receptor site 2, **Table 3**), as revealed by sodium flux (Catterall and Nurenberg, 1973; Catterall, 1977) and binding studies (Catterall, 1976; Couraud *et al.*, 1978; Jover *et al.*, 1978);
3. reveal a voltage dependent binding affinity to excitable membranes (Catterall, 1976), and a mutual displacability with the sea anemone As TxII (Catterall and Beress, 1978; Couraud *et al.*, 1978);
4. bind to the α subunit of the VGSC as observed by photoaffinity labeling (Beneski and Catterall, 1980; Sharkey *et al.*, 1984; Jover *et al.*, 1988); and
5. occupy loop linking segments S3 and S4 of domain IV of the α subunit of the VGSC as their receptor binding site (Rogers *et al.*, 1996; Benzinger *et al.*, 1998).

5.6.2.2.2. Beta toxins The β toxins differ from the α toxins and have the following characteristics:

1. They are derived, substantially, from the American buthid scorpion belonging to the subfamilies of Centrurinae and Tityinae.
2. They induce similar (but not identical) symptoms to those of the α toxins when assayed on intact animals (Martin-Eauclaire and Couraud, 1995).
3. Unlike the α toxins, the β toxins (Cahalan, 1975) induce repetitive firing, due to the appearance of an abnormal Na^+ current upon repolarization (Meves *et al.*, 1982; Wang and Strichartz, 1982; Simard *et al.*, 1986).
4. The β toxins bind to receptor site 4 (**Table 3**) of the sodium channel (Jover *et al.*, 1980; Barhanin *et al.*, 1982) and generate a shift in the voltage dependence of activation to a hyperpolarizing value (Vijverberg *et al.*, 1984; Jonas *et al.*, 1986).
5. The β toxins do not compete with α toxins in binding assays (Jover *et al.*, 1980), although both groups interact with the same sodium channels.
6. Unlike the α toxins, the binding of the β toxins is independent of membrane potential not modified by the lipophilic alkaloids (receptor group 2, **Table 3**) or sea anemone toxins (Jover *et al.*, 1988).
7. The receptor binding site of the β toxins on the VGSC was identified with the aid of chimeric sodium channels composed of combinations between segments derived from the mammalian skeletal muscle-brain sodium channel isoforms (which show that β toxins induced a negative shift in the voltage dependence of activation) and cardiac sodium channels (which are resistant to the β toxin voltage dependent activation). This approach showed that β toxins bind to loops S1–S2 and S3–S4 in domain II of the α subunit. These data also confirmed the critical role domain II plays in β toxin binding to sodium channels (see Section 5.6.4.3), particularly the G845 site in II S3–S4 loop. This amino acid is replaced by N in the β toxin resistant cardiac sodium channel (Cestele *et al.*, 1998; Cestele and Catterall, 2000).

5.6.2.3. Short Toxins

In addition to the two categories (α, β) of long scorpion toxins, which affect the VGSC, scorpion



venoms were shown to possess a series of "short" neurotoxins (30–40 amino acids, 2–3 disulfide bridges), which affect the conductance of voltage-gated potassium, calcium, and chloride channels. These short toxins are beyond the scope of this article, which focuses on the insect selective long chain VGSC scorpion toxins. However, the reader is urged to consult the reviews of Martin-Euclaire and Couraud (1995) and Loret and Hammock (2001). It appears that these short toxins, which were assayed largely in vertebrate systems, may serve as an additional source of insect selective neurotoxins.

5.6.2.4. Toxin Structures

The various α and β type VGSC scorpion toxins, when classified according to their phyletic specificity, binding properties, and electrophysiological effects, were recently (Possani *et al.*, 1999) subdivided into not less than 10 functional groups. Because of the importance of public health considerations, this section, however, deals with the so-called, "classical" α and β toxins that affect mammals and are represented by functional groups 1 and 2 in the review article by Possani *et al.* (1999). **Figure 7** provides the primary, covalent, and secondary structures of these classical mammalian toxins.

Fontecilla-Camps *et al.* (1980, 1982, 1988) have developed models of three-dimensional structures of scorpion toxins based on crystallographic data, computer graphics, and energy minimization. These models suggest spatial arrangements for the α and β toxins are similar. In spite of the diversity in their primary structure (Martin-Eauclaire and Couraud, 1995; Loret and Hammock, 2001), all toxins reveal a conserved hydrophobic surface, which is thought to be involved in interaction with the excitable membranes and their respective binding sites (Fontecilla-Camps *et al.*, 1982; Fontecilla-Camps, 1989).

It has been demonstrated (see above cited recent review articles) that all scorpion toxins share a similar basic molecular scaffold composed of four disulfide bridges and a highly conserved secondary structure, which has three stands of antiparallel β sheet (β_1, β_2, β_3) and one stretch of α helix. Covalent bonding between the α helix and the β sheet is specified in Section 5.6.4.1.1. A closer observation of the primary structures reveals diversified variable segments in the amino acid sequences, which occupy several regions (indicated by the gaps in **Figure 7**) in the primary structure. It has been proposed that these variable loop segments (Meves *et al.*, 1986; Jablonsky *et al.*, 1995; Possani *et al.*, 1999), are supposed to confer diverse pharmacological specificities. For further details the reader is urged to consult Possani *et al.* (1999) and Gurevitz *et al.* (2002). **Figure 7** demonstrates the arrangement of the secondary structures along the amino acid sequence, while **Figure 8** provides an example of the spatial arrangement of typical α and β toxins that are toxic to mammals.

Figure 7 Primary, secondary, and covalent structures of certain old world α toxins active on mammals (upper) and classical mammal specific β toxins (lower). Sequences were aligned in reference to Cys residues. Gaps were introduced to maximize similarities. Cys residues are numbered in the order they occur in the sequence. The regions of secondary structure are indicated in brackets above the sequences as α helices (α) and β strands (β). Abbreviations correspond to the scorpions: *Aa*H, *Androctonus australis* Hector; *Bot, Buthus occitanus tunetanus*; *Cn, Centruroides noxius* Hoffmann; *CsE, Centruroides sculpturatus* Ewing; *Css, Centruroides suffusus suffusus*; *Lqq, Leiurus quintquestriatus quinquestriatus*; *Ts, Tityus serrulatus*. 5.6.3. Insect Selective Neurotoxins: Pharmacology

5.6.3.1. The Pharmacological Ballet of Blowfly Larvae

5.6.3.1.1. The responsive larvae As indicated (see Section 5.6.2.4) scorpion toxins affecting the VGSCs, are presently subdivided into at least 10 functional groups. However, the three major groups of insect selective toxins, which are modifiers of the gating of the VGSCs, the excitatory depressant and α toxins, were detected on the basis of an intuitive observation of the behavioral response of blowfly larvae (Zlotkin *et al*., 2000).

Because blowfly larvae are continuously mobile with strictly segmented body musculature and have a soft and flexible integument, they can modify their mobility and body form in response to any disturbance in their neuromuscular system. As such, blowfly larvae provide a simple system to distinguish among the various insect selective toxins derived from scorpion venoms (**Figure 6**). Thus, excitatory toxins induce an immediate fast contraction paralysis (Zlotkin *et al*., 1971b, 1971c), while depressant toxins induce a preliminary transient contraction followed by a slowly progressing flaccid extension of the body (Zlotkin *et al*., 1991) (**Figure 6**). The alpha toxins show the so-called "delayed and extended contraction paralysis" (Eitan *et al*., 1990; **Figure 6**).

5.6.3.1.2. Isolation and purification The first scorpion venom derived insect selective neurotoxin was the excitatory toxin derived from the venom of *A. australis* Hector (AaIT). The isolation and purification of AaIT was monitored by the contraction paralysis assay of blowfly larvae (**Figure 6**). AaIT was isolated by using the column chromatography protocol developed by Miranda *et al*. (1970) for the purification of the first α toxins affecting mammals (see above). The protocol included water extraction, dialysis, recycling sephadex G50 gel filtration, and ion exchange equilibrium chromotography by anion (DEAE–Seph. A50) and cation (Amberlite, CG50) exchangers. However, presently, reverse phase columns are replacing the ion exchange chromatography (Eitan *et al*., 1990; Zlotkin *et al*., 1991). The final product, AaIT, contained 95% of the toxicity of the original venom, with a 267-fold increase in the specific toxicity. AaIT resembles other sodium channel scorpion neurotoxic polypeptides and comprises of a single chain polypeptide of 70 amino acids, cross-linked by four disulfide bridges. It is noteworthy that two additional AaIT isotoxins were isolated from the venom of *A. australis*: AaIT1, which differs by one amino acid (E25Q), and AaIT2, which differs by four amino acids (D2W, Y23N, E25Q, and P67T) (Loret *et al*., 1990a, 1990b). It was shown by modifications of Lys 28 or Lys 51 that these two amino acids are important for toxicity, and that their simultaneous modification led to a 40-fold reduction in insect toxicity. The primary structures of additional excitatory insect selective neurotoxins were derived from buthid scorpions such as *L. q. hebreaeus* (Froy *et al*., 1999), *L. q. quinquestriatus* (Kopeyan *et al*., 1990), *Buthus martensi* (Xiong *et al*., 1999), and *Buthotus judaicus* (BjxtrIT; Froy *et al*., 1999). With the exception of BjxtrIT toxin, these toxins had very similar amino acid sequences and identical location of the cysteine groups.

5.6.3.2. Complementary Duality of Excitatory and Depressant Toxins

5.6.3.2.1. Opposite as well as similar symptoms The blowfly larvae bioassay (**Figure 6a**) was used to monitor the purification of the excitatory insect selective toxins (Zlotkin *et al*., 1971a, 1985; Teitelbaum *et al*., 1979; Lester *et al*., 1982). The existence of depressant, flaccidity inducing insect toxins (such as BjIT2, LqqIT2, and LqhIT2) in Buthidae scorpion venoms was suggested by two pieces of evidence: (1) a progressive increase in the yield of the total contractive activity during the purification of the excitatory fly larvae-contractive toxins (Zlotkin *et al*., 1971a; Teitelbaum *et al*., 1979) suggested the removal of an antagonistic flaccidity inducing factor; and (2) the finding that venom of (*B. judaicus*), which is toxic to insects, did not induce in fly larvae the typical contraction paralysis but rather mixed, intermediate symptoms

that are between the two opposite forms of response presented in Figure 6a and b. Upon injection of 2 LD_{50} units of the crude venom into locusts, two phases of response were noticed. First, an immediate "knock-down" effect in the form of an excitatory paralysis (violent trembling of legs and contractions of thorax and abdominal muscles) for up to 30 min after injection. Second, after a partial recovery from this excitatory paralysis, there was a prolonged period of gradual progressive immobilization of the animal leading to death between 24 and 48 h following injection (Lester *et al.*, 1982). Subsequent systematic fractionation of the *B. judaicus* venom showed that the above duality in paralytic symptoms represents the presence of two categories of toxins that specifically affect insects, the excitatory and depressant toxins (Lester *et al.*, 1982). The depressant toxins, similar to the excitatory toxins, were shown to induce a transient short (1–2 s) phase of contractility that preceded the onset of flaccid paralysis (Figure 6b). As shown below, this similarity has additional manifestations.

5.6.3.2.2. Neuromuscular effects Simple considerations concerning symptomatology, doses, and speed of response indicated that the excitatory toxins, as well as the depressant toxins, substantially affected the nervous system.

The stimulatory action of the excitatory toxins on the skeletal musculature, as demonstrated in several insects (Zlotkin *et al.*, 1971a, 1971b; Walther *et al.*, 1976; Rathmayer *et al.*, 1978; Lester *et al.*, 1982), could have been attributed to either one or a combination of effects on the central nervous system (CNS), skeletal muscles, and/or peripheral motor neurons. Two separate lines of evidence, physiological and morphological, have clearly attributed the fast paralysis of the excitatory insect selective toxins to a presynaptic action, which is mediated by the terminal branches of motor nerves (Rathmayer *et al.*, 1978; Zlotkin, 1986; Fishman *et al.*, 1991). The latter conclusion is exemplified by Figure 9, which combines conventional electrophysiology and autoradiography to demonstrate that the peripheral terminal branches of the insect motor nerves are targeted by the excitatory AaIT toxin.

5.6.3.2.2.1. Depressant toxins LqhIT2 is a depressant toxin purified from the venom of the Israeli yellow scorpion. The effects of this toxin on prepupal housefly neuromuscular preparations mimic the effects on the intact animal (Figure 10), i.e., a brief period of repetitive bursts of junction potentials is followed by suppression of their amplitude and, finally, by a block of neuromuscular transmission.

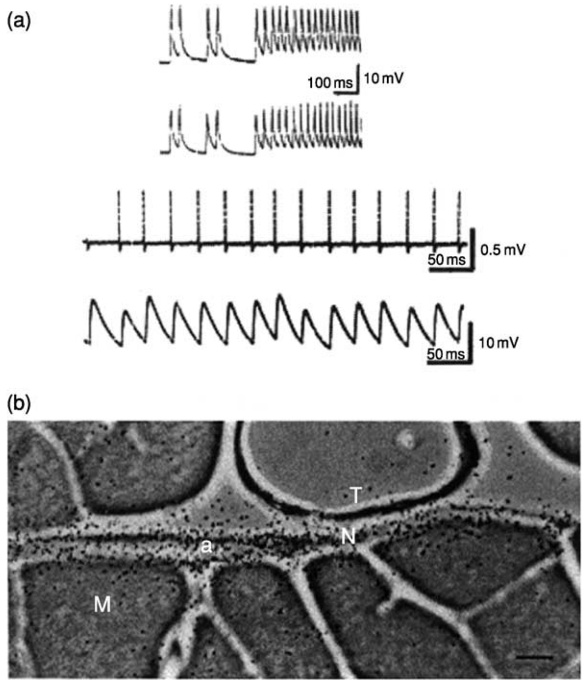

Figure 9 The peripheral terminal branches of the insect motor nerves are targeted by the AaIT. (a) Effect of AaIT on the neuromuscular preparation of the locust extensor tibiae muscle. Top: start of two trains of slow excitatory junction potential synchronously recorded from two distant locations on the muscle 50 min after application of 0.15 μg ml^{-1} of toxin. Bottom: spontaneous neuromuscular activity caused by toxin. Synchronous recording from the ''slow'' motor axon (upper trace) and a fiber in the main part of the extensor tibiae muscle (lower trace) 65 min after application of toxin. These data clearly indicate a presynaptic excitatory action on the motor nerve (Walther *et al.*, 1976). (b) Autoradiography of [^{125}I] AaIT in a terminal branch of motor nerve at its close proximity to the respective muscles in *P. americana* injected with a dose of the radioiodinated toxin, which induces fast paralysis. Note the obvious affinity of the toxin (photographic grains) to the nerves (N, nerve; a, axon) when compared to the surrounding muscles (M) and tracheae (T). (Reproduced with permission from Zlotkin, E., Fishman, Y., Elazar, M., **2000**. AaIT: from neurotoxin to insecticide. *Biochimie 82* (9–10), 869–881.)

Loose patch clamp recordings indicate that this repetitive activity has a presynaptic origin in the motor nerve, and closely resembles the effect of the excitatory toxin AaIT. The final synaptic block is attributed to neuronal membrane depolarization, which results in an increase in spontaneous transmitter release. This effect is not induced by the excitatory toxin which causes repetitive firing of the motor nerve (Figure 10d) and contraction of the larvae. The dominant effect of the depressant toxin is a complete block of neuromuscular transmission resulting in the final flaccid paralysis. In previous studies, using the cockroach ventral nerve cord derived giant axon, the insect specific depressant toxins LqqIT2 and $BjIT_2$ were shown

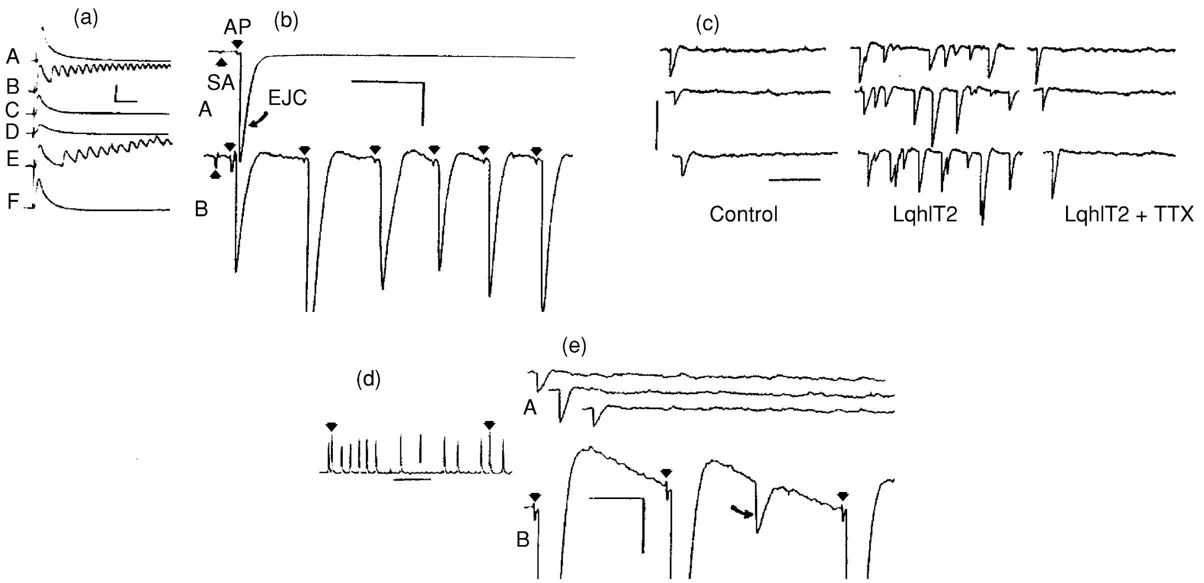

Figure 10 Neuromuscular effects of the depressant (LqhIT2) and excitatory (AaIT) insect toxins. (a) The depressant insect toxin LqhIT2 (40 nM) causes a brief phase of repetitive motor neuron activity followed by gradual suppression of excitatory junction potentials (EJPs) in prepupal *M. domestica*. (b) LqhIT2 induces repetitive presynaptic action potentials and excitatory junction currents (EJCs) in housefly muscle: (A) nerve stimulation (shown as a stimulus artifact, SA) generates a nerve terminal action potential (AP) resulting in an EJC of 2.7 nA amplitude; (b) following treatment with 30 nM LqhIT2, a single stimulus leads to repetitive action potentials (arrows) and EJCs. (c) LqhIT2 increases the spontaneous rate of neurotransmitter release, as measured by the frequency of miniature excitatory junction currents (MEJCs) recorded with a loose patch electrode. (d) AaIT induces repetitive activity in housefly motor neurons without suppressing EJPs or depolarizing the resting membrane potential of the muscle. Bath application of 125 nM toxin induces sporadic EJP activity. (e) Spontaneous junction current activity is shown before (A) and after (B) treatment with AaIT. No increase in spontaneous MEJC frequency was observed after treatment with AaIT. For details see text. For scorpion abbreviations see legend to **Figure 8**. (Reproduced with permission from Zlotkin, E., Eitan, M., Bindokas, V.P., Adams, M.E., Moyer, M., *et al.*, **1991**. Functional duality and structural uniqueness of depressant insect-selective neurotoxins. *Biochemistry 30* (19), 4814–4821.)

to block evoked action potentials, due to a tetrodotoxin sensitive depolarization of the insect axonal membrane and suppression of the sodium current (Lester *et al.*, 1982; Zlotkin *et al.*, 1985). The data presented in Figure 10 suggest that in the prepupal housefly preparation the blocking action of LqhIT2 is a consequence of membrane depolarization. Owing to the difficulty in measuring toxin induced changes in the motor nerve terminal directly, the depolarization was indirectly indicated by an increase in the frequency of miniature end plate junction potentials (MEJCs) (Zlotkin *et al.*, 1991). Such end terminal depolarization could sharply limit invasion of action potentials into nerve terminals and, thereby, suppress excitatory junction potential evoked transmitter release. The ability of very low LqhIT2 concentrations (5 nM) to increase MEJC frequency suggests that depolarization may be a primary effect of the toxin on the motor system. The absence of an increase in MEJC activity following AaIT treatment (Figure 10e) suggests that this excitatory toxin causes minimal, if any, depolarization of motor axon terminals. Its predominant effect is to produce sustained repetitive activity in the motor nerve (Figure 10d and e), as previously shown in a locust neuromuscular preparation (Walther *et al.*, 1976).

Thus, the excitatory toxin has a single effect on the motor nerve, inducing sustained repetitive activity, while the depressant toxin induces a transient phase of repetitive activity, followed by motor nerve terminal depolarization that produces the ultimate block of neuromuscular transmission. The distinctive characteristics differentiating excitatory (AaIT) from depressant (LqhIT2) insect toxins recall those previously observed with type I and type II pyrethroid insecticides. Like the excitatory toxins, the type I pyrethroids produce a slowing of sodium channel inactivation and repetitive action potential activity. In contrast, the type II pyrethroids, like the depressant insect toxins, primarily depolarize the resting membrane potential (Narahashi, 1986).

5.6.3.2.3. Effects on sodium conductance The mechanism of the AaIT's induced (see above) axonal repetitive firing was clarified by studies on an

isolated giant axon from the CNS of the cockroach *Periplaneta americana* (Pelhate and Zlotkin, 1981, 1982) in current and voltage clamp assays, using the double oil gap single fiber technique (Pichon and Boistel, 1967). The AaIT induced repetitive firing was accompanied by a 2–7 mV depolarization of the axonal membrane. Voltage clamp experiments were performed in the presence of 2×10^{-6} M diaminopyridine, thus selectively blocking potassium current (Pelhate and Pichon, 1974). Under voltage clamp, AaIT slowed Na^+ inactivation most effectively at low negative values of applied voltage and increased the peak sodium current by about 20%. It was concluded (Pelhate and Zlotkin, 1981, 1982) that the repetitive activity induced by AaIT results from the voltage dependent modulation of sodium inactivation coupled with an increase in sodium permeability. AaIT did not affect potassium current. The excitatory toxins BjIT1 (Lester *et al.*, 1982) and LqIT1 (Zlotkin *et al.*, 1985), when assayed on the cockroach isolated axonal preparation, have yielded data closely resembling those of the AaIT. Their induced repetitive firing is attributable to an increase of sodium conductance and the slowing of its turning off. Recent studies have supported the above basic conclusion by revealing that the excitatory toxins shift the threshold of insect sodium channel activation to a more negative membrane potential and increase peak sodium currents (Gordon *et al.*, 2002). The recently purified excitatory insect toxin (BjxtrIT, Froy *et al.*, 1999), when assayed on the identical system of the cockroach giant axon (Pichon and Boistel, 1967), has mimicked the AaIT toxin. In current clamp experiments, BjxtrIT depolarized the resting membrane potential and generated spontaneous action potentials (**Figure 11a** and **b**). In voltage clamp experiments, a series of voltage steps from the holding potential of −60 mV up to +50 mV, in the absence (control) and presence of the BjxtrIT toxin, revealed that BjxtrIT opens insect sodium channels at very negative potential values. This element is shown in **Figure 11d** in the form of the curves on relative sodium conductance under control conditions and in the presence of toxin. As shown, BjxtrIT causes a shift in the sodium activation voltage curve to more negative values by 12–15 mV.

An essentially similar result, namely a shift in the voltage dependent activation to more negative potentials, was revealed in the action of the AaIT toxin in central neurons of a lepidopterous insect, the tobacco budworm, *Heliothis virescens* (Lee and Adams, 2000). Neurons were prepared from thoracic and abdominal ganglia of male moths or last instar larvae. Neuronal sodium currents were obtained by whole cell recordings. The shift in voltage dependent activations is demonstrated in **Figure 12c**, which reveals that inspection of I/V curves before and after toxin exposure showed a shift in voltage dependent activation at more negative potentials. The shift in voltage dependent activation caused by AaIT is concentration dependent (not shown) (Lee and Adams, 2000).

The progressively developing flaccidity of experimental insects caused by the depressant toxins BjIT2 and LqIT2 was explained through data obtained using the *in vitro* cockroach axonal preparation (Lester *et al.*, 1982; Zlotkin *et al.*, 1985). The first effect was a progressive, irreversible depolarizing action, as shown by a continuous decrease in the value of the resting membrane potential. The second effect was the progressive suppression of the sodium current. The combination of these two effects explains the progressive block of the evoked action potentials. The blocking effect of the depressant toxins on axonal excitability may account for the induction of flaccidity and progressive paralysis in the test animals.

A more recent study (Ben Khalifa *et al.*, 1997) has clarified the mechanism of the blocking effect, emphasizing the fact that depressant toxins are sodium channel openers. This fundamental conclusion was reached in two successive studies employing the BotIT2 and the recombinant LqhIT2 depressant toxins on the isolated giant axon and isolated dorsal unpaired median (DUM) neuron of the American cockroach, under current and voltage clamp conditions, using the double oil gap and the patch clamp techniques, respectively (Stankiewicz *et al.*, 1996; Ben Khalifa *et al.*, 1997). In current clamp conditions, these toxins reproduce the effects previously seen with BjIT2 and LqIT2; namely, membrane depolarization, transient repetitive activity, and the occurrence of occasional plateau potentials upon artificial repolarization. However, the voltage clamp experiments in these studies were performed under voltage pulses of long duration (75–100 ms), and they reveal that the toxins target the sodium channel activation in a similar way to the β toxins affecting mammals (see above).

Accordingly, the clearest effect of the BotIT2 and LqhIT2 toxins is the development of a slow activating-deactivating sodium current, which follows or accompanies the previously seen decrease of the fast peak sodium current (**Figure 13**). It is noteworthy that a similar decrease of the peak sodium current is also induced by beta toxins (Wang and Strichartz, 1983), accompanied by the development of the slow sodium current (Meves *et al.*, 1982, 1984). Analysis of the above phenomena (Stankiewicz *et al.*, 1996;

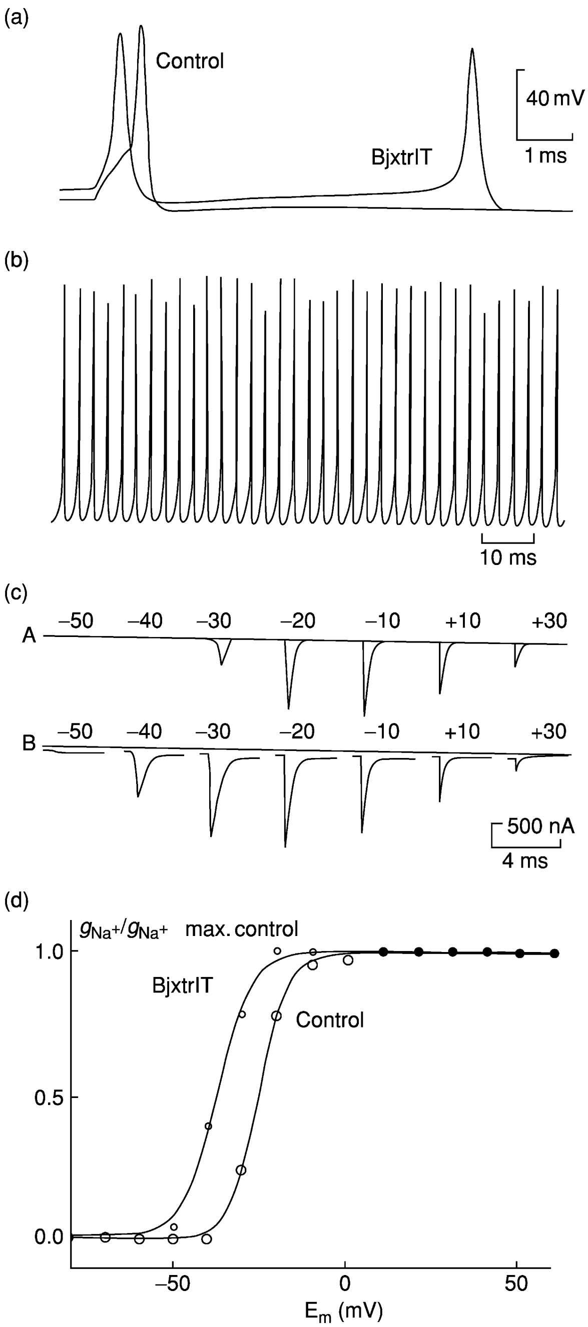

Figure 11 Effect of BjxtrIT on electrical activity and sodium currents of a cockroach isolated axon. (a) Two superimposed recordings of resting potentials and evoked action potentials under control conditions. A 0.5 ms current pulse of 10 nA evoked only one action potential of 95 mV in amplitude and 0.5 ms in duration (~20 mV above the resting potential). Six minutes after BjxtrIT application, the resting potential decreased by 6 mV; the action potential reached its threshold more rapidly and a second spontaneous action potential was measured 6.5 ms later, giving an instantaneous frequency of 154 Hz. (b) Spontaneous activity of the action potential after 7 and 10 min, respectively, after BjxtrIT application. Action potential frequencies higher than 200 Hz were obtained, and no ''plateau potentials'' could be measured. (c) Families of Na^+ currents recorded in the presence of 0.5 mM 3,4 diaminopyridine during 5 ms voltage pulses. (A): control; (B): after 6 min in the presence of Bj-strIT. Note that after BjxtrIT application, Na^+ currents developed at more negative potential values than in the control. The horizontal lines indicate the zero current level. (d) Voltage dependence of the sodium conductance (expressed as g_{Na^+}/g_{Na^+} max. control) calculated from current families as illustrated. Note the shift of the activation curve by 12.5 mV towards more negative potentials after addition of BjxtrIT. Bj, *Buthotus judaicus*. (Reproduced with permission from Froy, O., Zilberberg, N., Gordon, D., Turkov, M., Gilles, N., *et al.*, **1999**. The putative bioactive surface of insect-selective scorpion excitatory neurotoxins. *J. Biol. Chem. 274* (9), 5769–5776.)

Ben Khalifa *et al.*, 1997) has suggested that the balance between the fast transient and the slow sodium current components observed under BotIT2 and LqhIT2 would support the hypothesis of progressive toxin mediated transformation of fast-activating sodium channels into slow ones. The existence of two gating modes of sodium channels (fast and slow) has been reported in certain types of cells (Barres *et al.*, 1989; Kirsch and Brown, 1989),

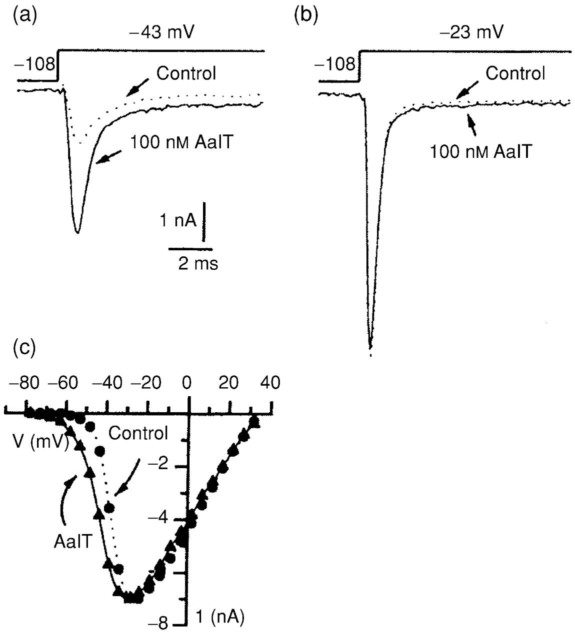

Figure 12 Voltage dependent action of AaIT (100 nM) on sodium channels in *H. virescens* neurons. (a) Peak sodium current evoked from a holding potential (V_T = −108 mV) to a test potential to −43 mV was more than doubled by AaIT, and steady-state sodium current also was increased. (b) Exposure to the toxin causes little change in peak or steady-state current at a test potential of −23 mV. (c) The current–voltage curve is shifted to more hyperpolarizing potentials in the voltage range −50 to −30 mV. (Reproduced with permission from Lee, D., Adams, M.E., **2000**. Sodium channels in central neurons of tobacco budworm, *Heliothis virescens*: basic properties and modification by scorpion toxins. *J. Insect Physiol. 46* (4), 499–508.)

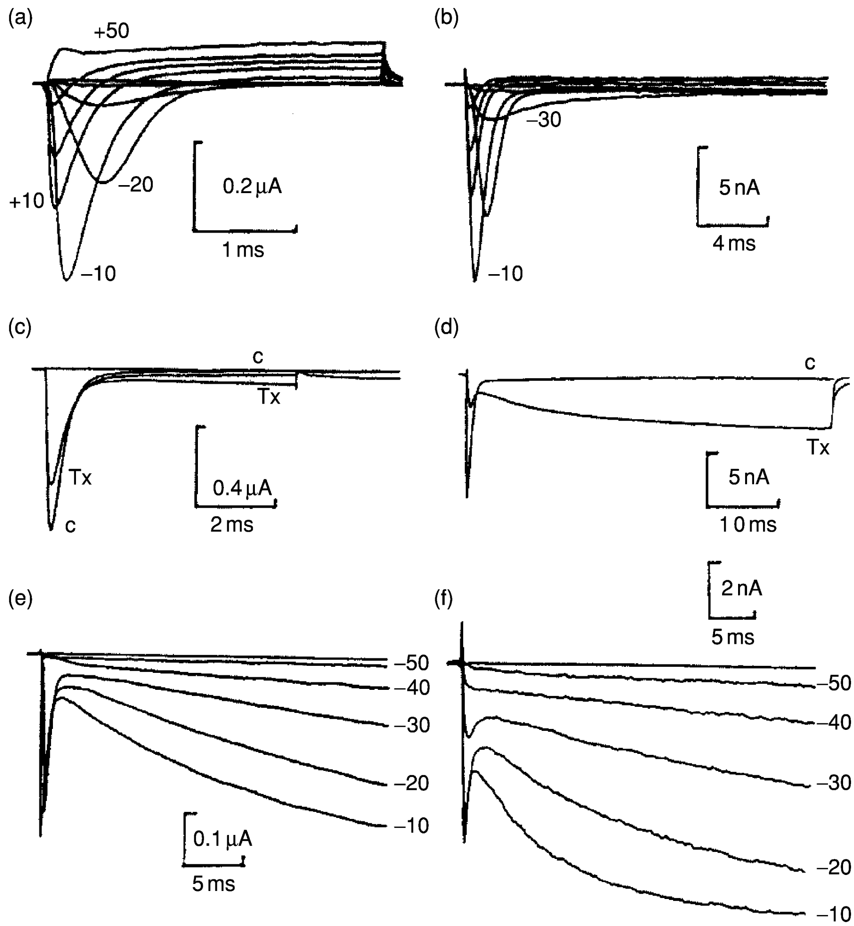

Figure 13 Transmembrane sodium currents recorded in giant axon (a, c, e) and in DUM neurone (b, d, f). (a, b) Control families of sodium currents recorded at different voltage pulses from a holding potential (HP) of −60 mV and −90 mV in axon and DUM neurone, respectively. (c, d) Superimposed sodium currents recorded before (c) and after application (Tx) of BotIT2 (1.5×10^{-6} M for axon and 3×10^{-6} M for DUM neurone). (e, f) Families of sodium currents after BotIT2. The pulse values are indicated near each trace. (Reproduced from Stankiewicz, M., Grolleau, F., Lapied, B., Borchani, L., el Ayeb, M., *et al.*, **1996**. BotIT2, a toxin paralytic to insects from the *Buthus occitanus tunetanus* venom modifying the activity of insect sodium channels. *J. Insect Physiol. 42* (4), 397–405.

where each channel switches between different structural conformations that underlie fast and slow gating. The toxins may interact with the above gating mechanism, transforming fast channels into slow ones. Furthermore, these slow currents may account for the global decrease in sodium peak conductance, which in turn accounts for the toxin induced flaccidity. In other words, the flaccidity is not due to a blockage of sodium channels, but rather to modified channels that open at more negative potentials and activate slowly. Thus, the depressant toxins are sodium channel openers.

5.6.3.2.4. Mutual displacability Differences in their primary structures, symptoms, and the effects on sodium conductance have raised the expectation that the excitatory and depressant toxins occupy separate receptor binding sites, similar to the α and β scorpion toxins affecting vertebrates. However, a series of competitive displacement binding assays, as shown in Figure 14, reveals that the radioiodinated AaIT toxin binding to locust synaptosomal membrane vesicles is displaced with a similar affinity by various excitatory and depressant insect selective toxins. Figure 15 reveals that the depressant LqhIT2 toxin possesses two noninteracting binding sites in locust neuronal membranes: a high-affinity ($K_{D1} = 0.9 \pm 0.6$ nM) and low-capacity ($B_{max} = 0.1 \pm 0.07$ pmol mg^{-1}) binding site, as well as a low-affinity ($K_{D2} = 185 \pm 13$ nM) and high-capacity ($B_{max} = 10.0 \pm 0.6$ pmol ng^{-1}) binding site. The data presented in Figure 16 reveal that the high-affinity site (responsible for the paralytic action) serves as a target for binding competition by the excitatory insect toxin AaIT. It is noteworthy that a scorpion β toxin (Ts VII), which was previously

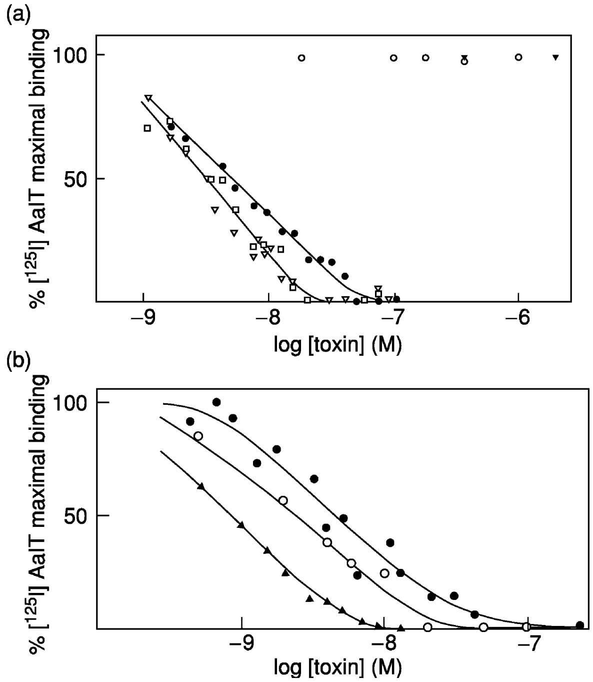

Figure 14 Displaceability of the [^{125}I] AaIT by the excitatory and depressant insect toxins. Ten microliters of the locust synaptosomal membrane vesicles (35 μg of protein) were added to 190 μl of the standard binding medium (0.15 M choline chloride, 1 mM $MgSO_4$, 2 mM $CaCl_2$, 0.1% BSA) containing 1.5 nM of [^{125}I] AaIT and increasing concentrations of each of the following unlabeled toxins: (a) AaIT (□); BjIT1 (●); BjIT2 (▽); AaMT2 (▼); *C. soffusus* β-mammal toxin 2 (○); (b) AaIT(○) LqIT1 (▲); LqIT2(●). The membranes were incubated for 30 min at 20–22 °C. For scorpion abbreviations see legend to **Figures 7, 10 and 11**. (Reproduced with permission from Gordon, D., Jover, E., Couraud, F., Zlotkin, E., **1984**. The binding of the insect selective neurotoxin (AaIT) from scorpion venom to locust synaptosomal membranes. *Biochim. Biophys. Acta 778*, 349–358; and Zlotkin, E., Kadouri, D., Gordon, D., Pelhate, M., Martin, M.F., *et al.*, **1985**. An excitatory and a depressant insect toxin from scorpion venom both affect sodium conductance and possess a common binding Site. *Arch. Biochem. Biophys. 240* (2), 877–887.)

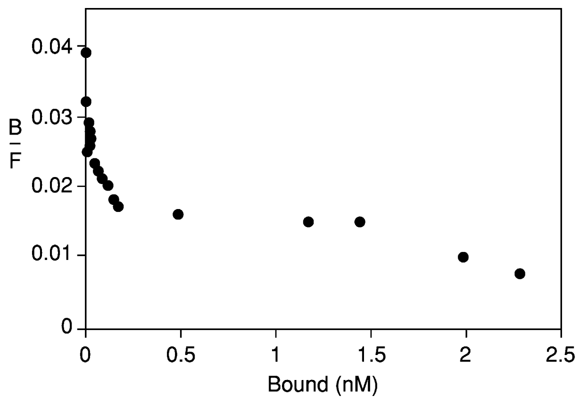

Figure 15 Scatchard analysis of a saturation curve of LqhIT2 binding to insect neuronal membranes. Locust neuronal membranes (155 μg of protein) were incubated with 72.5 pM [^{125}I]LqhIT2 and increasing concentrations of unlabeled LqhIT2 for 30 min at 22 °C in 0.4 ml of binding buffer, and the amount of specifically bound [^{125}I]LqhIT2 was determined following rapid filtration. Nonspecific binding (30–50% of total binding) was determined in the presence of 1 μM LqhIT2 and was subtracted from all data points. The concentration of LqhIT2 up to 5 μM did not reduce nonspecific binding. The specific radioactivity and the amount of bound toxin were recalculated for each toxin concentration, and the Scatchard plot was drawn using the computer program LIGAND. Scatchard plot analysis yielded the best fit ($P < 0.05$) using a two binding site model. The K_D values, obtained from three separate experiments, are $K_{D1} = 0.9 \pm 0.6$ nM, $B_{max1} = 0.1 \pm 0.07$ pmol per mg protein and $K_{D2} = 185 \pm 13$ nM, $B_{max2} = 10.0 \pm 0.6$ pmol per mg of protein. The total concentration of binding sites (R_T) used in the Hill plot was determined from Scatchard analysis. $N_H = 0.996$. For scorpion abbreviations see legend to **Figure 6**. (Reproduced with permission from Gordon, D., Moskowitz, H., Eitan, M., Warner, C., Catterall, W.A., *et al.*, **1992**. Localization of receptor sites for insect-selective toxins on sodium channels by site-directed antibodies. *Biochemistry 31* (33), 7622–7628.)

shown to compete with the AaIT on its binding sites in fly and cockroach CNS neuronal membranes (De Lima *et al.*, 1986), as well as with other β toxins in rat brain membranes (Barhanin *et al.*, 1982), was shown (Gordon *et al.*, 1992) to displace the [^{125}I] LqhIT2 from its high-affinity binding sites in the locust neuronal preparation as well. Thus, it may be concluded that the excitatory and depressant insect selective neurotoxins are able to mutually displace each other from a common receptor site. The latter is the high-affinity site of the LqhIT2 toxin, which is also shared by the β toxin TSVII (see below) (Gordon *et al.*, 1992). The above data suggested that the two different kinds of insect selective toxins either share a common binding site or possess separate, but mutually related, interacting binding sites on the insect neuronal sodium channel. The latter possibility, namely, separate binding sites, was suggested through the employment of site directed antibodies corresponding to conserved putative extracellular segments of the vertebrate sodium channels, coupled with binding assays of the radioiodinated AaIT and LqhIT2 toxins. These studies showed that the antibody mediated inhibition of [^{125}I] AaIT binding differs from that of LqhIT2 (Gordon *et al.*, 1992). Three out of the four antibodies that inhibited LqhIT2 binding only partially affected AaIT binding. These data suggest that the receptors to the depressant and excitatory insect toxins: (1) comprise an integral part of the insect sodium channel; (2) are formed by segments of external loops of the sodium channel; and (3) are in close proximity but are not identical in spite of the competitive interaction between these toxins (Gordon *et al.*, 1992).

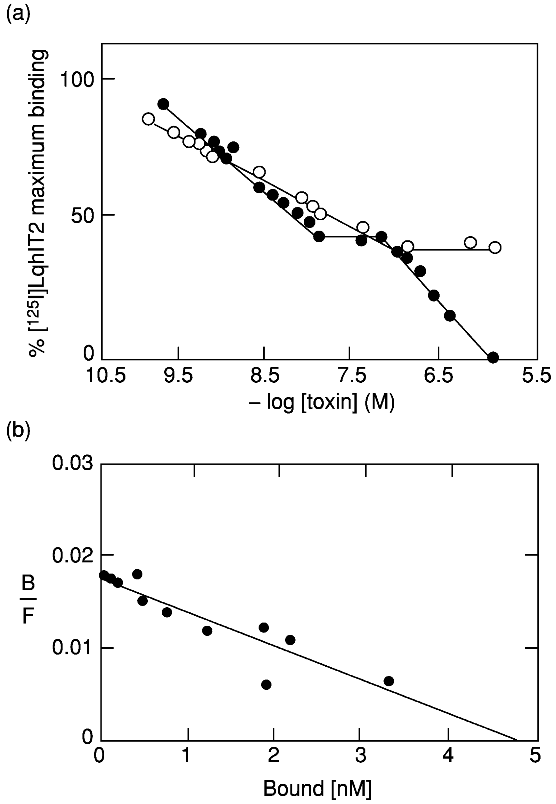

Figure 16 Displacement of [^{125}I]LqhIT2 binding by LqhIT2 and AaIT. Locust neuronal membranes were incubated for 30 min at 22 °C in the presence of 72.5 pM [^{125}I]LqhIT2 and increasing concentrations of LqhIT2. (●, 150 µg of membrane protein) or AaIT (○, 114 µg of membrane protein). Nonspecific binding of [^{125}I]LqhIT2, determined in the presence of 1 µM LqhIT2 was subtracted. The nonspecific binding was not affected by higher LqhIT2 concentrations, up to 5 µM. (a) Plots of [^{125}I]LqhIT2 bound as a function of log toxin concentration. (b) Scatchard analysis of a separate experiment in which 72.5 pM [^{125}I]LqhIT2 and 0.5 µM unlabeled AaIT (to saturate the high-affinity binding sites of LqhIT2) were incubated with 191 µg of locust membrane protein in the presence of increasing concentrations of unlabeled LqhIT2. The data were analyzed using the computer program LIGAND. The binding parameters of LqhIT2, representing the second low-affinity binding site, are $K_D = 194 \pm 36$ nM and $B_{max} = 13.8 \pm 6.9$ pmol per mg protein. (Reproduced with permission from Gordon, D., Moskowitz, H., Eitan, M., Warner, C., Catterall, W.A., *et al.*, **1992**. Localization of receptor sites for insect-selective toxins on sodium channels by site-directed antibodies. *Biochemistry 31* (33), 7622–7628.)

5.6.3.2.5. Complementary duality From a chemical ecology point of view the mutual displaceability among the excitatory and depressant toxins that occur in the same venom is puzzling. Such a paradox should have been eliminated by an evolutionary process. Its consistent occurrence in certain buthid venoms may suggest that it may fulfill an ecological role.

In Section 5.6.1.3, the change in composition of scorpion venom with the process of successive secretion is discussed. Lester *et al.* (1982) showed that a locust injected with *B. judaicus* crude venom displays a biphasic mode of paralysis, namely, a fast "knock-down," excitatory paralysis followed by a delayed progressive immobilization (similar to the effect of the depressant BjIT2 toxin) (see Section 5.6.3.2.1). Taking the above into account, it is tempting to assume that in successive venom secretions, the first released venom drops should contain predominantly excitatory toxin and that subsequent secretions should contain mainly the depressant toxin. The above possibility is supported by recent preliminary data based on blowfly larvae assays and RP-HPLC separation of buthid scorpion venom, indicating that the first stings contain mainly excitatory toxin while in subsequent stings, the depressant toxin predominates (Zlotkin, unpublished data).

An additional possibility is that the combined presence of the excitatory and depressant toxins fulfills a complementary or even cooperative role in the envenomated insect. Such an assumption is supported by the data presented in Figure 17 revealing a diversity in the mutual displaceability between the excitatory and depressant toxins in various insects. As shown in Figure 17, AaIT competes for all the high-affinity sites of LqhIT2 in cockroach and locust nervous system (Figures 15 and 16) and partially in the fly head neuronal membranes, but there is no displaceability between the two toxins in the lepidopterous larvae neuronal membranes. The insecticidal cooperativity towards noctuid larvae has been most recently revealed between an excitatory (LqhIT1) and a depressant (LqhIT2) toxin through the construct of a "double recombinant" *Autographa californica* nucleopolyhedrovirus (AcMNPV) (Regev *et al.*, 2003; see also Section 5.6.5.2). In other words the lack of competitive displaceability between the excitatory and depressant toxin (Figure 17; Moskowitz *et al.*, 1994) in the neuronal membranes of lepidopterous larvae enables the above insecticidal cooperativity.

5.6.3.2.6. The excitatory and depressant toxins are β toxins In the β toxin class, most toxins, which have been shown to be active on mammals, also show some activity against insects (Possani, 1984; De Lima *et al.*, 1986). The most selective group of toxins, which are toxic exclusively to insects, are the excitatory and depressant toxins. These toxins modify the activation process of the insect voltage-gated sodium channels (see Section 5.6.3.2.3). Therefore, these insect selective toxins represent the β toxin category among the Old World scorpion venoms (Stankiewicz *et al.*, 1996; Gordon, 1997a,1997b).

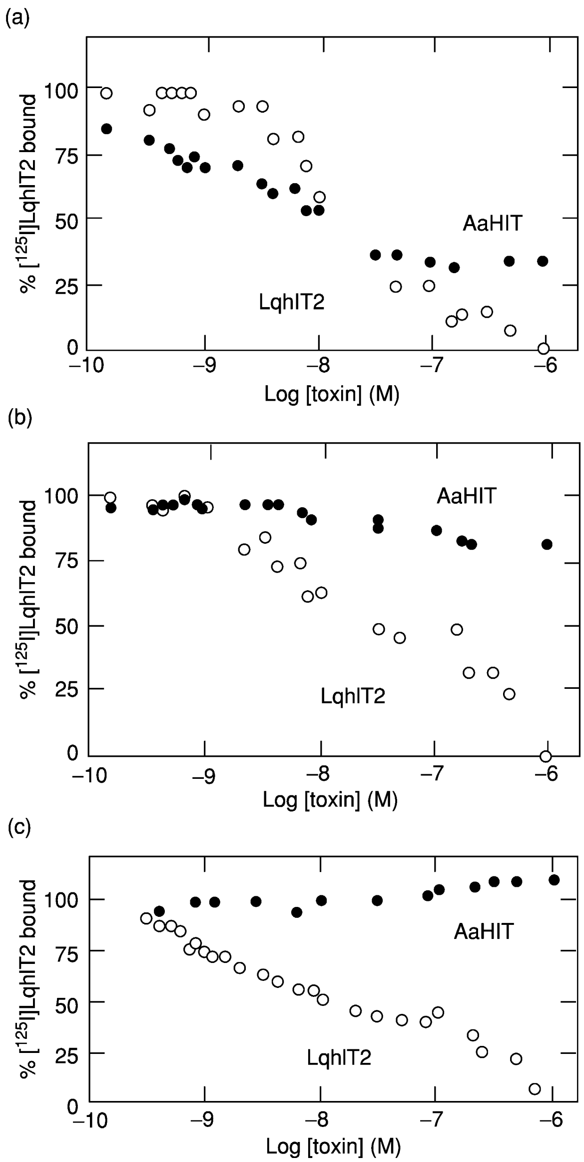

Figure 17 Competition for [^{125}I]LqhIT2 depressant toxin binding by the excitatory toxin AaHIT on various insect neuronal membranes. Neuronal membranes of (a) cockroach (*Periplaneta americana*), (b) blowfly head (*Sarcophaga falculata*), or (c) lepidopterous larvae (*Spodoptera littoralis*) were incubated for 1 h at room temperature in the presence of [^{125}I]LqhIT2 and increasing concentrations of AaHIT (●) or LqhIT2 (○). Nonspecific binding, measured in the presence of 1 μM LqhIT2, was subtracted. The depressant toxin reveals the two binding sites on every insect neuronal preparation while the excitatory AaHIT competes for all the high-affinity sites in cockroach (and locust), partially in fly and not at all in lepidopterous larvae neuronal membranes. For scorpion abbreviations see legend to **Figure 6**. (Reproduced with permission from Moskowitz, H., Herrmann, R., Zlotkin, E., Gordon, D., **1994**. Variability among insect sodium channels revealed by binding of selective neurotoxins. *Insect Biochem. Mol. Biol. 224*, 13–19.)

Two additional considerations support the similarity of the excitatory and depressant insect selective toxins to the β toxin category. First, their specific binding to the insect neuronal membranes is voltage independent (Gordon *et al.*, 1984; Moskowitz *et al.*, 1994) similar to that observed with mammalian sodium channels (Jover *et al.*, 1980; Lazdunski *et al.*, 1986). Second, the two categories of toxins were displaced by a typical β toxin (TS VII) from their binding sites in insect neuronal preparations. The latter was revealed in fly head synaptosomes using labeled excitatory AaIT toxin (De Lima *et al.*, 1986), and in locust synaptosomal vesicles by labeled depressant LqhIT2 toxin (Gordon *et al.*, 1992). Finally, the concluding remark of Stankiewicz *et al.* (1996) is noteworthy. They suggested that the excitatory and depressant toxins possess similar modes of action, and are distinguished essentially by their time course (kinetics). The depressant toxins drastically prolong the opening time of the sodium channel and, therefore, induce a depolarization that blocks neuronal conductance. The excitatory toxin induces a channel opening time of shorter duration, coupled to a voltage dependent slowing of inactivation, which favors the repetitive activity (Stankiewicz *et al.*, 1996).

5.6.3.3. Alpha Toxins Affecting Insects

5.6.3.3.1. LqhαIT toxin: the prototype This toxin was detected and isolated utilizing the blowfly bioassay monitoring a delayed and sustained contraction paralysis (**Figure 6c**; Eitan *et al.*, 1990). Like the excitatory and depressant insect selective neurotoxins, LqhαIT was highly toxic to insects, but it differed from these toxins in two important ways. First, LqhαIT lacked strict selectivity for insects. It was highly toxic to custaceans and had a measurable but low toxicity to mice. Second, it did not displace the excitatory toxin [^{125}I]-AaIT from its binding sites in the insect neuronal membrane. Such indicates the binding sites for LqhαIT are different from those shared by the excitatory and depressant toxins. However, in its primary structure (see **Figure 18**) and its effect on excitable tissues, LqhαIT strongly resembles the well characterized mammalian active α scorpion toxins. Its amino acid sequence was 55–75% identical with these α toxins. Such degree of similarity is comparable to that seen among the α toxins themselves. Voltage and current clamp studies showed that LqhαIT

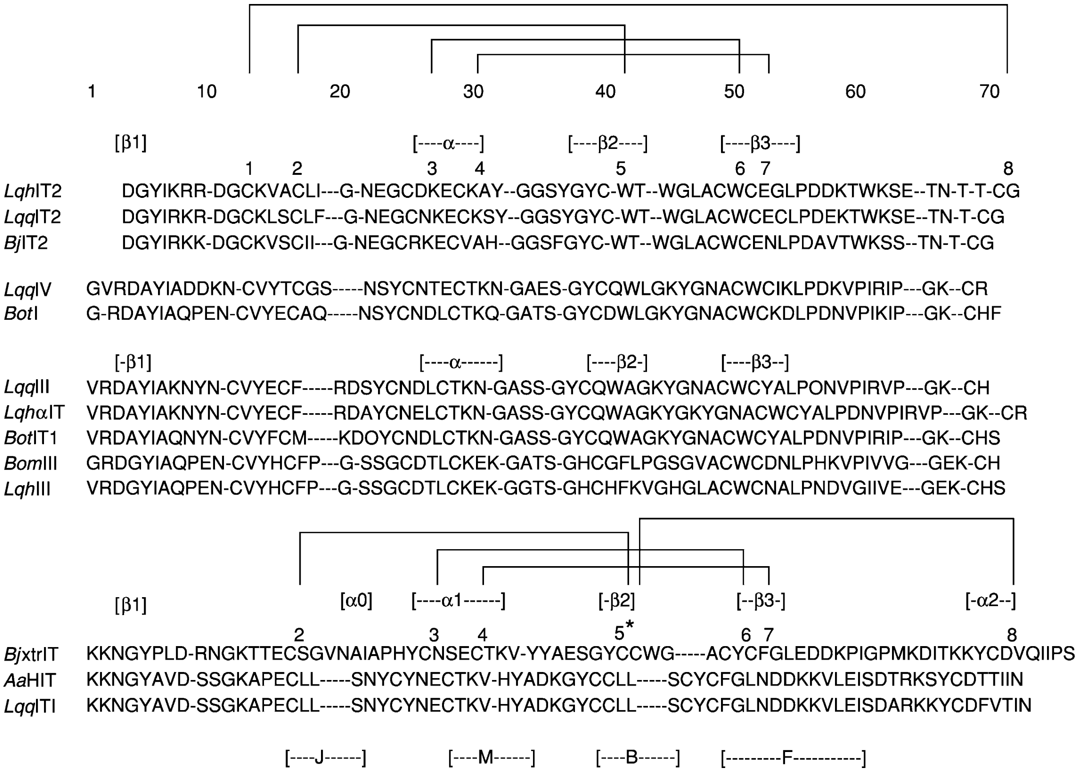

Figure 18 Primary covalent and secondary structures of representatives of the three major groups of the scorpion venom derived insect specific toxins affecting the VGSCs. Sequences were aligned taking as reference the Cys residues. Gaps were introduced in order to maximize similarities. Cys residues are numbered in the order of their appearance from N- to C-terminal. The regions of secondary structure revealed by three-dimensional studies are indicated in brackets above the sequences α (α helix), β (β strand). The asterisk on the right side of the fifth cysteine residue of the excitatory toxins indicates the position of the putative substitute of Cys 1 in the previous toxins. Bracketed J, M, B, and F regions at the bottom of the table indicate the position of the variable loops. Abbreviations correspond to the scorpions: *Aa*H, *Androctonus australis* Hector; *Bj*, *Buthotus judaicus*; *Bom*, *Buthus occitanus mordocei*; *Bot*, *Buthus occitanus tunetanus*; *Lqh*, *Leiurus quinquestriatus hebraeus*; *Lqq*, *Leiurus quintquestriatus quinquestriatus*. (Reproduced with permission from Possani, L.D., Becerril. B., Delepierre, M., Tytgat, J., **1999**. Scorpion toxins specific for Na^{+}-channels. *Eur. J. Biochem. 264* (2), 287–300.)

caused an extreme prolongation of the action potential in both cockroach giant axon (**Figure 19**) and rat skeletal muscle preparations, because of slowing inactivation of sodium currents. It has been concluded that LqhαIT is an α toxin, which acts on insect sodium channels (Eitan *et al*., 1990). However, due to its potential insecticidal value, a recent study that used neurons from thoracic and abdominal ganglia from the tobacco budworm, *H. virescens*, deserves attention (Lee and Adams, 2000). When treated with LqhαIT, in contrast to the excitatory AaIT, the toxin was shown to slow channel inactivation dramatically without modifying voltage dependent activation (**Figure 20**). Lee and Adams (2000) suggested that the differences in the poisoning symptoms of AaIT and LqhαIT can be explained by their different effects on sodium conductance. AaIT causes stimulus independent spontaneous action potentials in injected insects and *in vitro* neuromuscular preparations (see Section 5.6.3.2.2) leading to the typical symptoms of tetanic paralysis. In contrast, LqhαIT did not have any effect on the activation, but strongly inhibits the inactivation process. These considerations provide a reasonable explanation for the fact that LqhαIT causes repetitive activity only when motor axons are previously activated, leading to hyperactivity but not tetanic contractions (Lee, 1997).

5.6.3.3.2. The pharmacologic diversity of the α toxins As shown in Section 5.6.2.2, α scorpion toxins slow sodium current inactivation in various excitable preparations (Gordon and Gurevitz, 2003). The mammalian VGSCs are expressed by a gene family, which produce at least 12 known sodium channel subtypes that are distinguished by their location in various excitable tissues and their TTX sensitivity. Scorpion α toxins serve as a proper tool

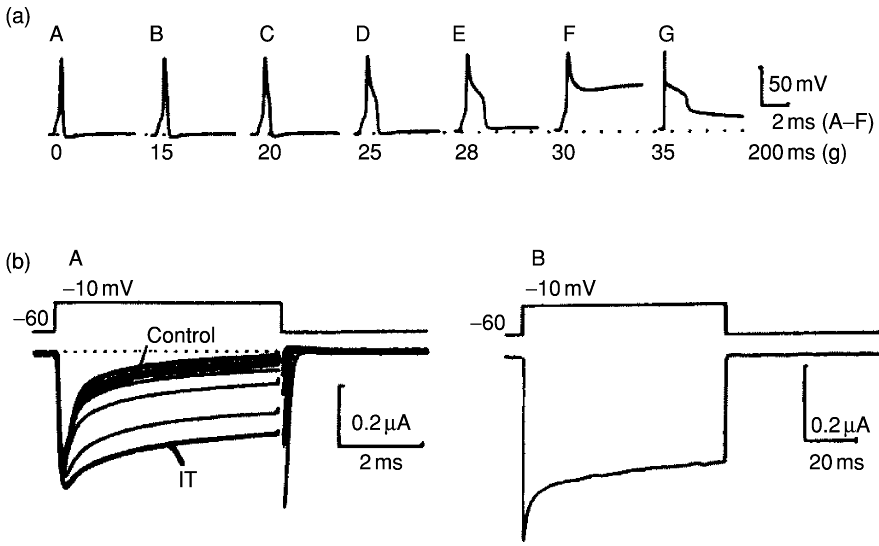

Figure 19 Effect of LqhαIT toxin on action potentials and sodium currents of isolated insect axon. (a) Effect on action potentials of the isolated cockroach axon. (A–G) Records of action potentials evoked by a short (0.5 ms) depolarizing current pulse of 10 nA. The number under the records indicates the time in minutes. Note the different time scale in grams. (b) Effect of LqhαIT toxin (10^{-6} M) on the sodium current of the isolated cockroach axon – a voltage-clamp experiment in the presence of 2×10^{-4} M 3,4-diaminopyridine. (A) Superimposed records of the sodium currents. In the control, the sodium current completely inactivates in less than 6 ms. In the presence of LqhαIT toxin (IT), the sodium inactivation is progressively slowed. The records were made every 20 s. (B) Record of the maintained sodium current. This record, which shows a very slow decrease in the sodium inward current during the voltage pulse, was taken 3 min after LqhαIT application. The slowest time constant was 250 ms instead of about 2.0 ms as observed in the absence of toxin. (Reproduced with permission from Eitan, M., Fowler, E., Herrmann, R., Duval, A., Pelhate, M., *et al.*, **1990**. A scorpion venom neurotoxin paralytic to insects that affects sodium current inactivation: purification, primary structure, and mode of action. *Biochemistry 29* (25), 5941–5947.)

for the identification of the various mammalian sodium channels (Gordon *et al.*, 2002). Thus, α toxins could have been subdivided according to their preference for mouse brain or rat synaptosomes, their abilities to affect rat brain sodium current or rat pyramidal neurons current, or even to distinguish between skeletal muscle, cardiac muscle, or motor nerve sodium channels (Gilles *et al.*, 1999, 2000; Gordon *et al.*, 2002). However, from a strictly entomological point of view, the scorpion α toxins are currently subdivided into three categories: (1) the "classical" α toxins, such as AaH2 and Lqh2, which are active in the mammalian brain; (2) α toxins that are very active in insects, namely LqhαIT and Lqq3 (Gordon *et al.*, 2002); and (3) α-like toxins, such as Lqh3, Bom 3, and Bom 4, which are unable to displace AaH2 (Gordon *et al.*, 2002). These toxins are active in both the mammalian and insect CNS.

All scorpion α toxins compete with the LqhαIT binding site on the insect VGSC receptor site 3 (**Table 3**). However, their binding affinity for insect and various mammalian sodium channels, as well as their voltage dependence and allosteric modulation by other channel toxicants, varies greatly (Gordon *et al.*, 1996, 2002; Gilles *et al.*, 2001, 2002).

5.6.4. Insect Selective Neurotoxins: the Molecular Level

5.6.4.1. Structure–Function Relationships

5.6.4.1.1. Primary, secondary, and tertiary structures **Figure 18** shows the primary covalent and secondary structures of the depressant, the excitatory, and the α insect specific toxins (Possani *et al.*, 1999). The depressant and the α insect specific toxins possess the typical structural arrangement revealed by the vertebrate affecting α and β toxins (Section 5.6.2.4; **Figures 7 and 8**), namely, a single chain of about 60–65 amino acids cross-linked by four disulfide bridges and a conserved secondary structure composed of an α helix adjacent to a triple-stranded antiparallel β sheet (see Section 5.6.2.4). The helix motif is linked to the β_3 strand by two of the four disulfide bonds (Cys 3 and 4 connected to Cys 6 and 7). A third, structurally conserved disulfide bond is the one between the Cys residues 2 and 5. These three conserved bonds occur in all scorpion toxins (including the excitatory insect specific toxins and the sodium channel blockers) (Possani *et al.*, 1999), and they play a role in the stabilization of the structurally conserved core of scorpion toxins. The fourth disulfide bridge in

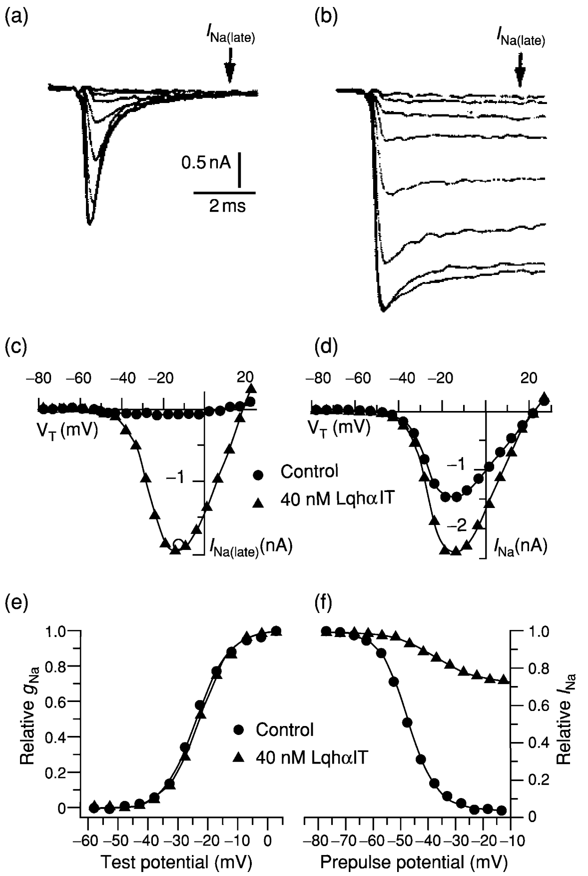

Figure 20 Effects of LqhαIT on sodium channels in cultured larval *H. virescens* neurons. (a) Superimposed sodium currents evoked by V_Ts from −48 to −13 mV (in 5 mV intervals) prior to the toxin exposure. (b) LqhαIT (40 nM) inhibited channel inactivation and increased peak sodium currents. (c) Late sodium currents $I_{Na(late)}$ taken at the time indicated by down arrows in (a) and (b) plotted as a function of test potential before (●) and after (▲) application of LqhαIT. $I_{Na(late)}$ was elevated in a voltage-dependent manner by LqhαIT. (d) *I–V* curves for peak sodium current before (●) and after (▲) application of LqhαIT. (e) Data from (d) are plotted as relative sodium conductance (g_{Na}), showing that the toxin did not modify voltage dependent activation of sodium channels. (f) Inhibition of steady-state inactivation by LqhαIT. Note that all sodium channels were inactivated by a −15 mV prepulse prior to toxin treatment, while ~70% of sodium channels failed to inactivate under the same conditions after application of the toxin. (Reproduced with permission from Lee, D., Adams, M.E., **2000**. Sodium channels in central neurons of the tobacco budworm, *Heliothis virescens*: basic properties and modification by scorpion toxins. *J. Insect Physiol. 46* (4), 499–508.)

the long-chain toxins is established between Cys residues adjacent to N- and C-terminals – Cys 1 and Cys 8 (Figure 18).

As shown in Figure 18, the fourth disulfide bond in the excitatory insect specific toxins is formed between the additional Cys residue in their β_2 strand (replacing Cys 1) and the C-terminal Cys 8 residue. However, this difference in the covalent bonding of the excitatory toxins does not affect the overall

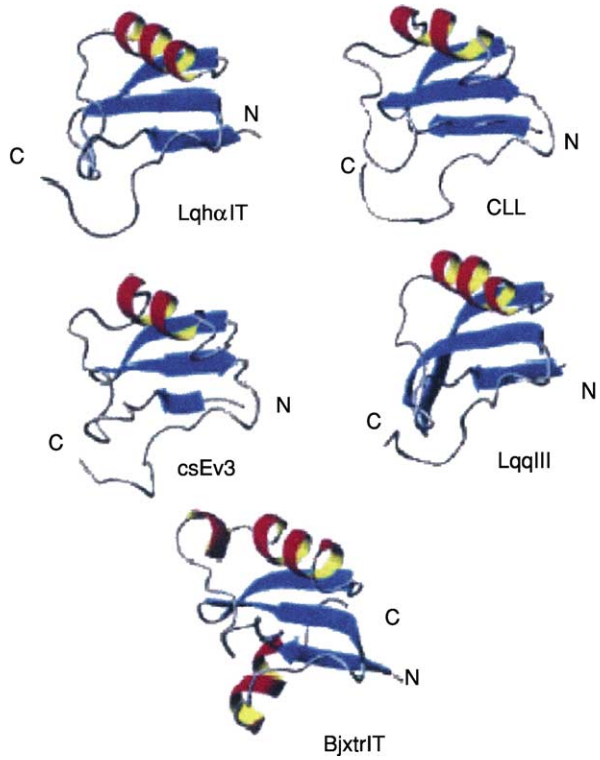

Figure 21 Spatial arrangement of some representatives of buthid scorpion toxins affecting arthropods. All toxins are similarly oriented with N- and C-terminals shown. LqhαIT is an insect specific α toxin. CLL is a crustacean toxin. CsEv3 is lethal to crickets. LqqIII is an α-like toxin that affects sodium inactivation in insects. BjxtrIT is an insect selective excitatory toxin; it is the only one that possesses two α helices. (Reproduced with permission from Possani, L.D., Becerril, B., Delepierre, M., Tytgat, J., **1999**. Scorpion toxins specific for Na^+-channels. *Eur. J. Biochem. 264* (2), 287–300.)

folding and spatial arrangements of these molecules (Figure 21). The various conserved elements of secondary structures are connected by variable loops, which are solvent exposed turns (the bracketed J, M, B, and F regions at the bottom of Figure 18), and these correspond to the most structurally variable regions of the toxin considered to be responsible for their pharmacological specificity. A recent study by Froy *et al.* (1999) reports the isolation of a new insect selective toxin (BjxtrIT) from the venom of the Black Judean scorpion (*B. judaicus*) which, in spite of its higher molecular mass (76 amino acids, 8455 Da) and only 49% sequence identity, mimics the mode of action of AaIT. Although the spatial arrangement of BjxtrIT resembles the basic pattern of the scorpion neurotoxins it reveals two unique segments when compared to other excitatory toxins. First, it possesses five additional amino acid residues just before the α helix motif. In this extra region, the three-dimensional analysis revealed the presence of an α helix. The second peculiarity of this molecule

is the formation of an additional short α helix by residues 63–69 (**Figure 21**).

5.6.4.1.1.1. Functional groups of the VGSC active scorpion neurotoxins Use of a diverse set of experimental systems that allowed testing of various animals, neuronal preparations, and molecular approaches enabled a more detailed subdivision of the VGSC active scorpion neurotoxins (Gordon, 1997b; Gordon *et al.*, 1998, 2002). Possani *et al.* (1999) divided these toxins into 10 functional groups, according to their mode of action and animal group specificity: (1) classical mammal toxic α toxins with AaHII as prototype (Possani, 1984; Kirsch *et al.*, 1989; Gordon, 1997); (2) classical mammal toxic β toxins (Jover *et al.*, 1980; Couraud *et al.*, 1982; Zamudio *et al.*, 1992; Dehesa-Davila *et al.*, 1996); and (3) β toxins with dual, mammal/insect specificity, mediated by separate receptors. This latter group is represented by toxin Ts7 (Ts gamma) (De Lima *et al.*, 1986, 1989; De Lima and Martin-Eauclaire, 1995); (4) depressant insect selective neurotoxins (Zlotkin *et al.*, 1991); (5) α toxins affecting insects not very specifically, as represented by LqhαIT toxin (Eitan *et al.*, 1990) and LqqIII toxin (Kopeyan *et al.*, 1993); these toxins inhibit sodium inactivation and displace AaH2 (Possani *et al.*, 1999); (6) excitatory insect selective neurotoxins represented by the AaIT and BjxtrIT toxins (Zlotkin *et al.*, 1971c; Froy *et al.*, 1999); (7) New World toxins active against insects and crustaceans (Lebreton *et al.*, 1994; Selisko *et al.*, 1996; Garcia *et al.*, 1997); (8)–(10) it also includes three additional groups of various intermediate forms, weakly affecting insects and vertebrates (Possani *et al.*, 1999). The above subdivisions represent the pharmacologic flexibility of scorpion neurotoxins, but the rules governing the structure–function relationships still remain to be determined.

5.6.4.1.2. Bioactive surface and positive charges A key concept in understanding the biological role of a protein is that its function is derived from its three-dimensional structure. In monomeric proteins, such as the scorpion toxins, the tertiary structure is the highest level of organization. In spite of their functional diversity, scorpion toxins reveal a conserved spatial arrangement, which is formed by the disulfide covalent linkage between the α helix and the β sheet strands (see Section 5.6.4.1). The expected disagreement between the conserved structure (**Figures 18 and 21**) and their pharmacologic diversity can be demonstrated by two examples: the first reveals a large difference in action between two molecules that possess a strong spatial similarity, and the second reveals a pharmacological similarity between two molecules that differ in their spatial folding. For example, the toxin AaHSTR1, derived from the dangerous scorpion *A. australis*, is not toxic in spite of the fact that it exhibits a primary structure and a spatial arrangement similar to β-type mammal toxic scorpion toxins (Blanc *et al.*, 1997). The structure is composed of a short α helix (residues 26–33) connected by a tight turn to a triple stranded antiparallel β sheet (sequences 3–6, 38–41, and 44–48). The second contrary example is provided by comparison of the α scorpion toxins and sea anemone toxins, which compete on the receptor site 3 of the VGSC and inhibit sodium inactivation (**Table 3**). BgII, similar to other sea anemone toxins, is a short protein (4–5 kDa) cross-linked by three disulfide bridges (Kem and Dunn, 1988). As shown in **Figure 22** it is devoid of an α helix and its entire folding differs from that of the α AaH2 scorpion toxin. Superimposition of the three-dimensional structures of the above toxins (**Figure 22**) reveals four basic amino acid residues located in similar position and orientation. Such features may form two positively charged poles on the surfaces of both toxins. These aspects of the toxin surface and positive charge deserve further attention.

The above structure–function dilemma of scorpion toxins is better rationalized by the notion of an interplay between two structural motives; the scaffold provided by the covalently stabilized secondary structure serves as a supporter of a more variable entity the “bioactive surface.” Protein surface is of interest because it is the part of the protein that is accessible to another molecule and, hence, is where ligands bind. The accessible surfaces of molecules can be localized and mapped based on hydrophobicity and charge. It is generally accepted that the molecular basis for specific binding interactions lies in the uneven charge distribution over the surface of the protein (Stryer, 1995). It has been proposed that long chain scorpion toxins, which act on sodium channels, have on their surface a group of aromatic and hydrophobic residues. These residues are localized in a “conserved hydrophobic surface,” which include the toxins’ active domain (Fontecilla-Camps *et al.*, 1988; Landon *et al.*, 1997). Bearing this in mind, it is noteworthy that scorpion toxins are basic proteins in which the positive charge seems to be critical for binding. For example, Bot-XI is structurally homologous to AaH2, but is much less potent presumably due to the replacement of a surface lysine, position 58 in AaH2 (Sampieri *et al.*, 1987). Furthermore, chemical modifications of lysine residues in scorpion toxins strongly decrease their toxicity (Sampieri and Habersetzer-Rochat,

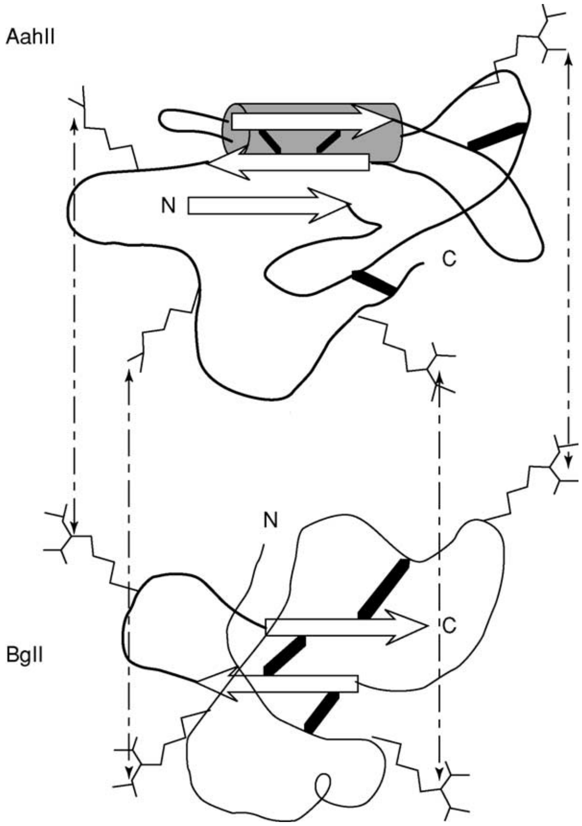

Figure 22 Comparison of structures for scorpion toxin AahII and a sea anemone toxin BgII. Although different in overall structure, the two toxins compete for the same binding site on the sodium channel. Superimposition of the two structures reveals four basic amino acid residues (dashed double-headed arrows) located in the same position within the two proteins (Arg 62, Lys 58, Lys 50, and Arg 18 in AahII and Arg 5, Arg 14, Arg 27, and Arg 36 in BgII (Loret *et al.*, 1994). (Reproduced from Loret, E., Hammock, B.D., **2001**. Structure and neurotoxicity of venoms. In: Bronwell, P., Polis, G. (Eds.), Scorpion Biology and Research. Oxford University Press, Oxford, p. 204.)

1978; Loret *et al.*, 1994). Similarly, chemical modification of conserved basic residues between the α helix and β sheet of AaIT (**Figure 18**) decreases its toxicity without markedly changing toxin binding affinity (Loret *et al.*, 1990a,1990b). A further discrepancy between toxicity and binding affinity was demonstrated by the ancestral scorpion toxin AaHIT4, which binds to the insect sodium channel with the same affinity as the AaIT, but has much lower toxicity (Loret *et al.*, 1991). The importance of the basic residues is exemplified in **Figure 22**.

5.6.4.2. Structural Features of the Insect Selective Toxins

5.6.4.2.1. The approach In the past, chemical modifications of specific amino acids served as the main approach to the study of toxicity–structure relationships (Darbon *et al.*, 1983; el Ayeb *et al.*, 1986; Kharrat *et al.*, 1989). However, using molecular biology techniques it is now possible to perform site directed mutagenesis of small peptides through the *Escherichia coli* expression system (Gurevitz and Zilberberg, 1994; Zilberberg *et al.*, 1996; Gurevitz *et al.*, 1998, 2002). Such studies are now feasible because genes encoding the most potent anti-insect α toxin, LqhαIT, and the excitatory BjxtrIT toxin have been isolated from cDNA libraries made from the telsons of *L. q. hebraeus* and *B. judaicus* (Zilberberg *et al.*, 1991; Zilberberg and Gurevitz, 1993; Froy *et al.*, 1999). The resulting expressed and renatured toxins have mimicked the native, chemically purified toxins in toxicity, binding, and electrophysiological assays (Zilberberg *et al.*, 1996; Turkov *et al.*, 1997; Froy *et al.*, 1999). The availability of a fully active recombinant toxin, coupled with site directed mutagenesis and structural analysis, facilitated elucidation of the toxins' bioactive surfaces.

5.6.4.2.2. The bioactive surface The issue of the functional diversity of the α toxin subtypes (see Section 5.6.3.3.2) was submitted to an intensive molecular treatment (Gurevitz *et al.*, 2002), including the most recent functional expression of chimeric toxin constructs (Gordon and Gurevitz, 2003). Briefly:

- The α toxins Lqh2 and LqhαIT, which reveal a very close similarity in their three dimensional structures (Gurevitz *et al.*, 2002) represent the classical mammal and insect active subtypes, respectively. LqhαIT binds to insect VGSCs with high affinity, but is almost devoid of any binding to rat brain sodium channels. Lqh2 binds with high affinity to rat brain VGSC, but with very low affinity to the insect sodium channels.
- Mutagenesis of LqhαIT (more than 40 point mutations) has revealed two sets of amino acids that constitute the bioactive surface, namely: F17, R18, W38, N44 and Y10, R58, V59, K62 (Gurevitz *et al.*, 2002) (**Figure 23**).
- The above information has suggested an active site exchange. That in the structural elements that carry the bioactive residues have been exchanged between the two toxins, resulting in chimeric constructs that acquired the functional selectivity of the "donor" toxin (Gordon and Gurevitz, 2003). These results emphasize similarity in the localization of bioactive surfaces on various α toxins, and that small differences on these surfaces dictate the pharmacological selectivity of these toxins (Gordon and Gurevitz, 2003).

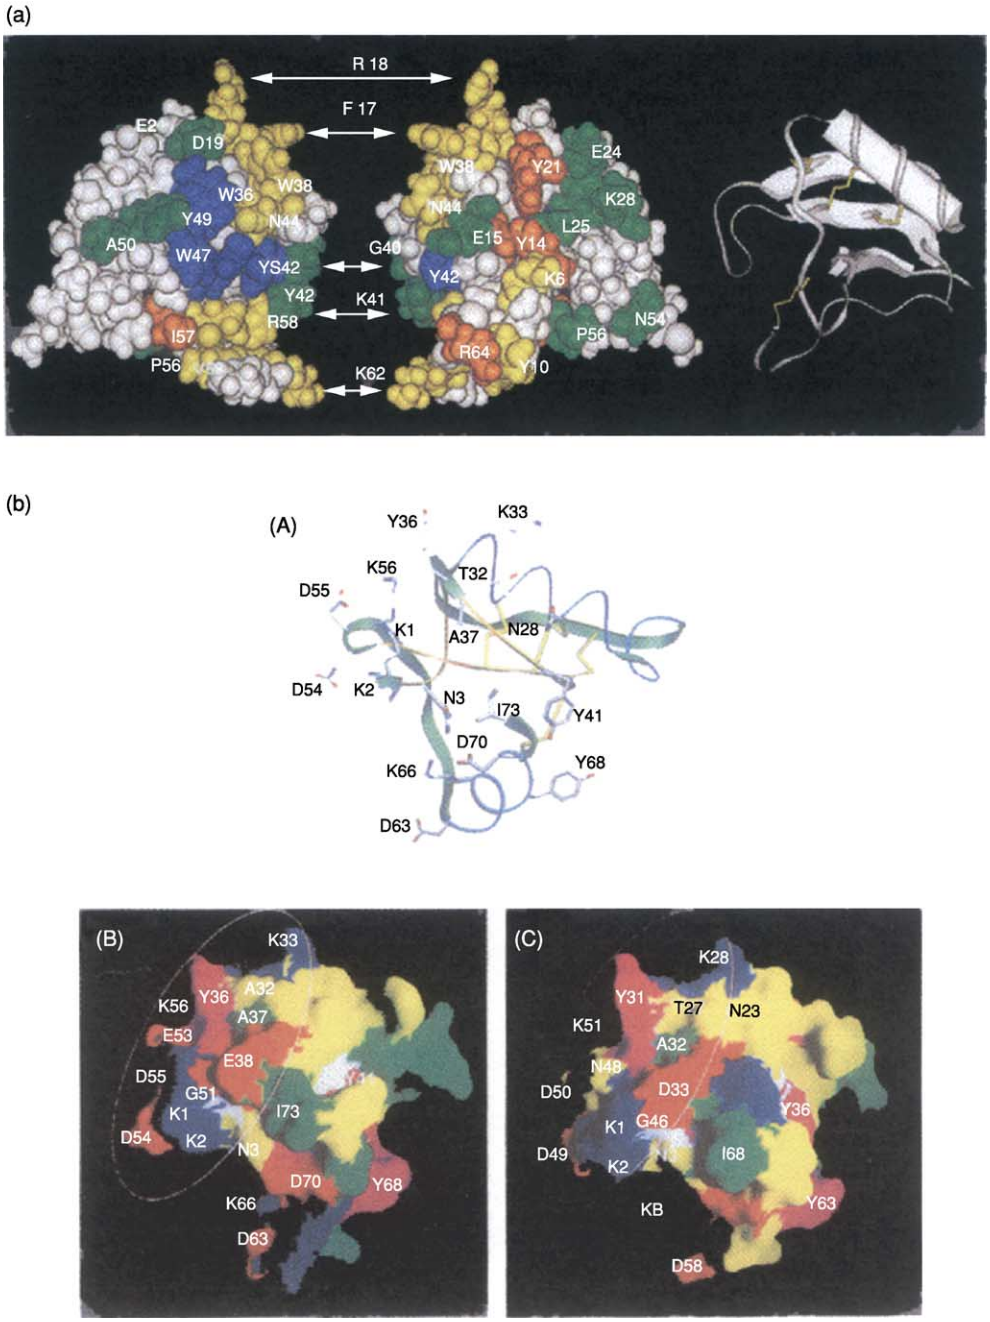

Figure 23 The putative bioactive surfaces of LqhαIT and BjxtrIT. The three-dimensional models are based on the solution and crystal structures, respectively. (a) LqhαIT with identical orientation of the carbon backbone (right) and the space-filling model (middle). Modified residues affecting bioactivity are in yellow and orange. Residues, which belong to the ''conserved hydrophobic surface'' are in blue. (b) Putative bioactive surface of scorpion excitatory toxins: (A) a ribbon diagram of the BjxtrIT structure (Oren *et al.*, 1998) with the side-chain residues indicated in panel B; (B, C) the putative bioactive surfaces of BjxtrIT and AaIT, respectively, highlighted by the ellipsoid (for details see Froy *et al.*, 1999). (Reproduced with permission from Gurevitz, M., Zilberberg, N., Froy, O., Turkov, M., Wilkunsky, R., **2002**. Diversification of toxin sites on a conserved protein scaffold – a scorpion recipe for survival. In: Menez, A. (Ed.), Perspectives in Molecular Toxinology. Wiley, Chichester, pp. 239–253.)

5.6.4.2.3. The structural uniqueness of the excitatory toxins: the C-terminal stretch The AaIT excitatory toxin has two structural characteristics namely the extension of the C-terminus and the formation of a different disulfide bridge (Darbon *et al.*, 1982). Both are confined to a region adjacent to the conserved hydrophobic surface thought to be implicated in the toxic activity (Fontecilla-Camps,

1989; Figure 18). A two-dimensional nuclear magnetic resonance study of the AaIT toxin (Darbon *et al.*, 1991) suggested that differences in their selectivity are due to the position of the C-terminal peptides with respect to the hydrophobic surface (see below).

The functional significance of the C-terminal region was emphasized by a recent study with the excitatory toxin BjxtrIT (Froy *et al.*, 1999). The toxin was submitted to an extensive mutagenesis of amino acids that are on the surface. Out of the 26 mutations introduced, substitutions of Asp 55, Asp 70, Ser 76, Asn 28, and Tyr 36 caused a fivefold reduction of toxicity, while substitution of the C-terminus hydrophobic residues Ile 73 and Ile 74 had a much larger effect of over 100-fold toxicity reduction (Froy *et al.*, 1999). Use of a similar approach with LqhαIT and the depressant LqhIT2 further emphasized the pharmacological role of the C-terminus. Mutations of LqhαIT revealed that substitution of Lys 8, Tyr 10, Phe 17, Arg 18, Arg 58, Val 59, and Lys 62, each reduced toxicity fivefold. The latter three belong to the C-terminal tail, and the other amino acids contribute to the outer surface. Similarly, in LqhIT2, the residues Asn 58 and Gly 61 of the C-terminal tail and Asp 8 Lys 11 and Lys 26 of its adjacent bioactive surface, when modified showed a fivefold decrease in toxicity.

In excitatory toxins, however, the C-terminus dictates the entire design-form of the active surface. Figure 24 demonstrates a superposition of the α backbones of four categories of scorpion toxins affecting VGSCs, and it exemplifies the 180 degree positional shift of the C-terminal tail of BjxtrIT and its fourth disulfide bridge, when compared to the other toxin categories. As shown in Figure 24, the shift of the C-terminal tail dictates (in reference to the scaffold) the orientation of the bioactive surface, which comprises the distal part of the C-terminal tail.

It has been suggested that the phyletic specificity of scorpion toxins is mediated by the "evolutionary wiggling of the C tail" (Gurevitz *et al.*, 2001), as performed by virtue of the change in the fourth disulfide bridge (Figure 24) in the excitatory insect selective toxins (Gurevitz *et al.*, 2002). Given this background of the hypothetical "evolutionary tail wiggling" it is noteworthy that a previous study of Loret *et al.* (1990b) suggested a "pharmacological" C tail wiggling. The significance of the C-terminal segment was indicated by a circular dichroism (CD) study with the dual active TSVII toxin. This β toxin was shown to affect insects through an AaIT receptor and affect mammals through the receptor of a potent mammal toxin β toxin (De Lima *et al.*, 1986). It has been suggested that when in contact

Figure 24 Superposition of the Cα backbone of scorpion toxins affecting sodium channels. Four toxins representing distinct pharmacological groups are delineated in ribbon: the α toxin, LqhαIT, the β toxin Cn2, and the excitatory toxin, BjxtrIT have blue, magenta, and red C-tails, respectively. Note: the last three residues could not be seen in the X-ray structure of BjxtrIT, but they cover, most likely, residue 38 in the center of the bioactive surface. In addition, a model of a depressant toxin, LqhIT2, is presented with a green C-tail (the model was constructed by alignment with Cn2 using the MODELLER and HOMOLOGY modules of Insight II, MSI, Cambridge, UK). The α helix and β strands are highlighted (barrel and arrows, respectively). The conserved three disulfide bonds are depicted in yellow lines, whereas the fourth disulfide bond is pinpointed in yellow balls and sticks. (Reproduced with permission from Gurevitz, M., Zilberberg, N., Froy, O., Turkov, M., Wilkunsky, R., **2002**. Diversification of toxin sites on a conserved protein scaffold – a scorpion recipe for survival. In: Menez, A. (Ed.), Perspectives in Molecular Toxinology. Wiley, Chichester, pp. 239–253.)

with the insect sodium channel, a supplementary α helix in the C-terminal region from residues 51 to 60 is formed (which is similar to the one described for the AaIT) (Loret *et al.*, 1990b; Figure 18), and this might endow the TSVII toxin with insect sodium channel binding properties. Conversely, the formation of a supplementary antiparallel β strand might give the TSVII its ability to bind to mammalian-type sodium channels, as with the β-type toxins (Loret *et al.*, 1990b). To summarize, the dual functions of the TSVII are attributed to a presumably adaptive modification of secondary structure and the conformational flexibility of the C-terminal region.

5.6.4.3. Interaction with the Insect VGSC

5.6.4.3.1. The voltage-gated sodium channels The pharmacology of VGSCs was reviewed previously by Catterall (1980, 1992, 1995), Gordon

(1997b), and Goldin (1999). For insecticidal aspects, the reader is referred to recent review articles by Bloomquist (1996), Zlotkin (1999), chapters in Clark (1995), Ishaaya (2001), and Section 5.6.5, as well as Section 5.6.1.4.3.. Briefly, VGSCs mediate an increase in sodium permeability during the initial rapidly rising phase of action potential in excitable tissues. They are plasma membrane proteins composed of a large pore-forming α subunit that is generally accompanied by one or two auxillary subunits (Feng *et al.*, 1995; Shichor *et al.*, 2002). The α subunit is composed of four repeated domains (D1–D4), each consisting of six transmembrane α helix segments (S1–S6) and a pore loop (between segments S5 and S6) (Catterall, 1995). Modifiers of VGSCs are used as drugs (Kallen *et al.*, 1993) and insecticides (Zlotkin, 1999) in spite of their limited and harmful lack of specificity to channel subtypes.

As shown in **Table 3**, voltage-gated sodium channels are the molecular targets for a broad range of neurotoxins that act at at least six distinct receptor sites on channel protein. These toxins can be subdivided into three categories: (1) toxins that physically block the pore and prevent sodium conductance comprised of hydrophilic compounds of low molecular mass and larger polypeptide toxins; (2) alkaloid toxins and related lipid soluble toxins that alter voltage dependent gating of sodium channels via an allosteric mechanism, through binding to intramembranous receptor sites; and (3) polypeptide toxins that alter channel gating by voltage sensor trapping through binding to extracellular receptor sites (Cestele and Catterall, 2000). The excitatory and depressant scorpion toxins belong to the latter category, but they are also able to exclusively identify insect VGSCs, and are able to distinguish between insect and their vertebrate-mammalian counterparts.

5.6.4.3.2. Domain II is targeted by the insect selective β toxins

5.6.4.3.2.1. The chimeric channel The aim of a study by Shichor *et al.* (2002) was to clarify the selective basis of AaIT toxin interaction with insect VGSCs by localizing the region that is targeted by the toxin. The approach taken was dictated by the following four considerations:

1. Insect VGSC is the exclusive target for excitatory as well as depressant toxins (see above and Zlotkin *et al.*, 2000).
2. Because of its mode of action AaIT belongs to the major β category of scorpion venom neurotoxins (see Sections 5.6.3 and 5.6.2.6).
3. The β toxins shift the voltage dependence of activation to more negative potentials (Section 5.6.3.2.6) by binding to receptor site 4 (Catterall, 1992). This site was shown to be in domain II (D2) (Marcotte *et al.*, 1997; Tsushima *et al.*, 1999) and includes the external loop S3–S4 of the vertebrate VGSC (Cestele *et al.*, 1998).
4. It has been assumed that like in mammalian channels, the β toxin site on insect channels also resides in D2 and is thereby targeted by AaIT.

With this background, a chimeric mammalian–insect channel composed of the rat brain sodium channel (rBIIA), in which D2 was replaced by the Para (paralytic temperature sensitive) *Drosophila* sodium channel D2, was constructed. As shown below, the chimeric channel was functional, despite a large phylogenetic distance between insects and mammals, and acquired the sensitivity to the anti-insect selective toxin AaIT.

The approach was comprised of construction of a chimeric cDNA (using restriction nucleases and PCR), generation of the respective cRNA, injection into *Xenopus* oocytes, and monitoring the sodium current by the two-electrode voltage clamp method (Shichor *et al.*, 2002).

5.6.4.3.2.2. The chimeric channel as susceptible to AaIT The main body of information is presented in **Figure 25** and its legend. First, in contrast to the insect Para channel, the mammalian rBIIA is not sensitive to AaIT (**Figure 25a**). Second, the chimeric channel is functional, as demonstrated by its capacity to produce voltage-gated sodium currents, which are sensitive to TTX and are regulated by the mammalian auxiliary subunit β1 (**Figure 25b**) but not by the insect TipE auxiliary subunit. The latter is consistent with the finding that the binding site for the β1 subunit was localized on domain D4 in the RBIIA channel (Qu *et al.*, 1999). Third, the chimera, similar to the *Drosophila* Para/TipE and in contrast to the RBIIA/β1 subunit, acquired sensitivity to the AaIT toxin (**Figure 25c**).

Analysis of the voltage dependence of activation of the chimeric channel revealed a statistically significant negative shift of 6 mV in V1/2; in the presence of AaIT (**Figure 25c**, middle and bottom). This effect resembles the negative shift in the voltage dependence of activation of sodium currents in insect neurons induced by AaIT (see Section 5.6.3.2.2 and Lee and Adams, 2000). The responsiveness of the chimeric channel to AaIT revealed an additional characteristic of the β toxins. Similar to the effect of the β toxin Css-IV on the rat brain rBIIA

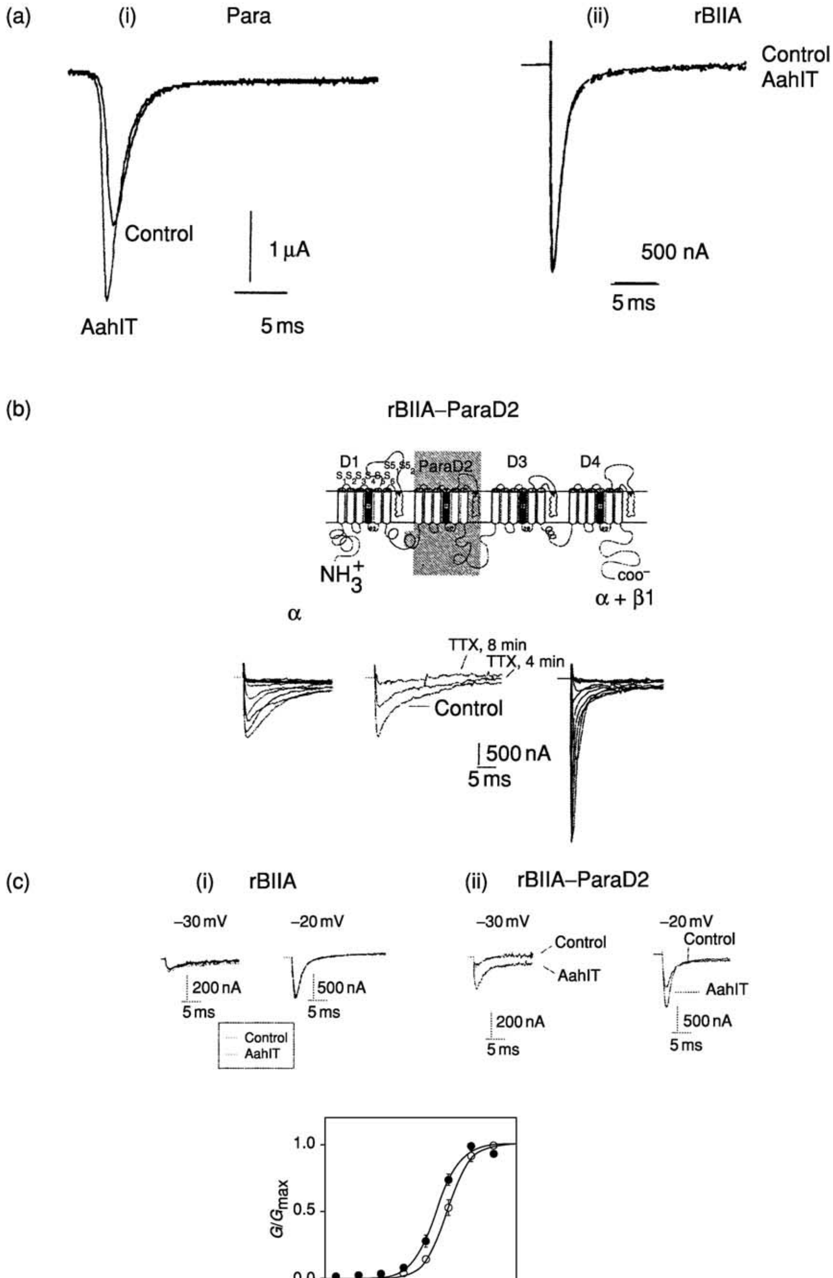

Figure 25 Domain II of *Drosophila* Para voltage-gated sodium channel confers sensitivity to AaIT toxin as revealed by sodium currents recorded from recombinant *Xenopus* oocytes in voltage clamp assays. (a) The rat brain channel (rBIIA) in contrast to the insect Para channel is not sensitive to the excitatory insect selective toxin (AaIT). (i) Para together with its auxiliary subunit TipE responds to 1 μM AaIT. (ii) rBIIA together with the auxiliary β1 subunit is resistant to 3 μM AaIT. (b) The expressed chimeric channel α subunit (α) is able to produce sodium currents (left) in a TTX sensitive (middle) and β1 (right) dependent fashion. (c) AaIT affects the rBIIA–Para D2 chimera but not the rBIIA channels. Top panel: currents elicited after step depolarization to −30 or −20 mV before and 10 min after application of 3 μM (i) or 1.4 μM (ii) AaIT. Concentrations up to 10 μM were checked to give the same results. Bottom panel: normalized conductance (G/G_{max}) voltage relationships. ○, control; ●, AaIT. Note the negative shift in the voltage dependence of activation of the sodium currents. (Reproduced with permission from Shichor, I., Zlotkin, E., Ilan, N., Chikashvili, D., Stuhmer, W., *et al.*, **2002**. Domain 2 of *Drosophila* para voltage-gated sodium channel confers insect properties to a rat brain channel. *J. Neurosci. 22* (11), 4364–4371.)

channel (Cestele *et al*., 1998), a depolarizing conditioning prepulse (to +50 mV) potentiated the effect of AaIT on the chimeric rBIIA-Para D2 currents. It may be concluded that the phyletic selectivity of AaIT is conferred by D2 of the insect VGSC (Shichor *et al*., 2002). Owing to the mutual displaceability between the excitatory and depressant toxins (see Section 5.6.3.2.4), and their assignment to the β toxins category, it appears that domain II also provides the binding region for the depressant toxins.

The above-demonstrated homology in the β toxin receptor sites between insect and mammalian sodium channels raises the question whether the external loop S3–S4 in D2 of the mammalian (RBIIA) channel, shown to comprise the receptor binding site for the β scorpion toxins (Cestele *et al*., 1998), also provides the binding site for the insect selective neurotoxins on the insect VGSC. The data presented in **Figure 26** show that the S3–S4–D2 loop is highly conserved in insect Para, rat brain, and skeletal muscle sodium channels. Furthermore, the Gly 845 residue in the RBIIA is essential for the binding of TsVII β toxin (Cestele *et al*., 1998), or its equivalent Asn residue in the cardiac channels. Both residues were shown to occur in the Para channels of fruit flies, domestic flies, and cockroaches. Therefore, it has been suggested (Gordon *et al*., 2002) that a separate or additional region in the insect Para D2 is most likely involved in the selective recognition by the excitatory (and depressant) insect selective scorpion neurotoxins of insect sodium channels.

Scorpion toxins differentiating among neuronal sodium channel subtypes: nature's guide for design of selective drugs. In: Menez, A. (Ed.), Perspectives in Molecular Toxinology. Wiley, Chichester, pp. 215–238.)

However, in spite of the above structural homogeneity between the insect and mammalian VGSCs, it may be safely concluded that domain D2 determines the selectivity of the AaIT toxin to insects.

5.6.5. Applicative Agrotechnical Aspects

Recent progress in the fields of molecular biology and biotechnology has enabled the practical employment of pharmacologically useful polypeptides. The agronomical usefulness of insect selective neurotoxic polypeptides follows from (1) the growing public awareness to health hazards and environmental damage, and (2) the evolution of insect resistance, both of which derive from the massive use of classical industrial insecticides. The plant protective utility of the insect selective toxins is based on a combination of the following technical possibilities: their mimicry by nonpeptidic agents, their inclusion in recombinant insect infective microorganisms, the design of modified insect gut permeable polypeptides, their inclusion in transgenic insect protected plants, or their combined application with conventional insecticides. The section below addresses some of these aspects.

5.6.5.1. Baculoviral Bioinsecticides

5.6.5.1.1. Recombinant baculoviruses The technology of insecticidal recombinant baculoviruses has been the subject of several reviews (Maeda, 1989; Bonning and Hammock, 1992, 1996; O'Reilly *et al*., 1992; Loret and Hammock, 2001; see also Section 5.6.5). Given this broad background, focus is on key aspects specifically related to the scorpion venom insect selective neurotoxins. Owing to its proteinaceous nature and inaccessibility by topical or oral applications, the insect selective AaIT toxin cannot serve as a classical insecticide. Furthermore, it has a low toxicity to lepidopterous larvae (see below and Section 5.6.3.2.5), major pests of field crops. This problem is solved when the insecticidal action of AaIT is mediated by a recombinant baculovirus.

Baculoviruses are insect specific pathogens used as biological, environmentally clean insecticides. However, the baculoviruses act slowly enabling the insect pest larvae to feed continuously on the crop. This drawback is solved through the use of genetically engineered baculoviruses, which express genes encoding insecticidal neurotoxins (Bonning and Hammock, 1996). The foreign gene is subcloned into a transfer vector plasmid, which is cotransfected with parental baculovirus DNA into an appropriate insect cell line, so that the foreign gene

is transferred to the baculovirus by homologous recombination. The infectivity of baculoviruses is limited to a few closely related species within a single insect family. Thus, an important factor in the environmental safety of baculoviral insecticides chosen for their species selectivity is the fact that they complement natural predators instead of replacing them, as in the case of many chemical insecticides. Naturally occurring viruses are evolutionarily adapted for self-preservation and propagation. It follows that a part of the baculovirus replication strategy is to keep its host alive as long as possible to maximize progeny production. Genetic engineering is used to improve the efficacy of the viruses as pesticides by reducing the time it takes the virus to stop their insect hosts feeding (Bonning and Hammock, 1996).

5.6.5.1.2. The tolerance of lepidopterous larvae to AaIT The interaction of the fast-acting, neurotoxic and insect selective polypeptide AaIT with lepidopterous larvae tissues was studied through assays of toxicity, chromatography, binding, and autoradiography. The native and/or radioiodinated toxin was shown to induce a delayed, slow, progressive paralysis (within 24–28 h) of *Spodoptera* larvae at relatively high doses (paralytic unit: 2.4 μg/100 mg). The larvae of six species representing five families of Lepidoptera responded similarly to the toxin. The toxin is stable *in vitro* using insect hemolymph; however, 80% of its toxicity is lost in the insect's body within 24 h, accompanied by a progressive process of degradation and elimination by the excretory system. The toxin is devoid of accessibility to peripheral-terminal branches of *Spodoptera* motor nerves *in situ*, strongly contrasting with those of the toxin susceptible *Periplaneta* nerves (**Figure 9**).

It was concluded that the tolerance of lepidopterous larvae to AaIT can be substantially attributed to pharmacokinetic aspects of toxin accessibility barriers and degradation processes (Herrmann *et al.*, 1990). However, a subsequent study (Fishman *et al.*, 1997) revealed the occurrence of a pharmacodynamic aspect in the tolerance of lepidopterous larvae. This aspect was demonstrated in studies of the kinetics of binding dissociation of [^{125}I]AaIT from neuronal membranes of susceptible and tolerant insects. Stable binding is shown in susceptible insects such as cockroaches and locusts, which have a dissociation half time of approximately 9 and 5 min, respectively. This contrasts strongly with the fast half-times of dissociation of 7 s in *Spodoptera littoralis* (Noctuidae: Lepidoptera) larvae and 9 s for the terebrionid beetle *Trachyderma philistina* (Coleoptera), which are both relatively tolerant to AaIT. Such differences in binding kinetics may reflect a structural and functional diversity of sodium channels in different insect species that is responsible for their diverse susceptibilities to neurotoxic polypeptides.

To summarize, it has been shown that the relative tolerance of lepidopterous larvae to the AaIT toxin is based on a combination of two separate groups of factors. First, these are those that affect the accumulation of the critical dose at the site of action (the so-called pharmacokinetic factors), such as toxin impermeability of the terminal motor branches (**Figure 9**) and its degradation and elimination process. Second, these are factors that affect AaIT interaction with its receptor site pharmacodynamics as revealed by fast dissociation ($t1/2 =$ seconds) from lepidopterous neuronal membranes, strongly contrasting with susceptible insects ($t1/2 =$ minutes) (**Table 6**, **Figure 27**). As shown below, the above tolerance is overcome by the aid of an AaIT expressing recombinant baculovirus.

5.6.5.1.3. AaIT expressing recombinant baculoviruses In spite of the relative tolerance of lepidopterous larvae to the excitatory toxin, several laboratories have been designing AaIT based

Table 6 Paralytic potency and dissociation constants of AaIT in various insects and their respective neuronal membranes

Species	*PD$_{50}$*[a] *(μg 100 mg^{-1} body mass)*	*$10^{-3} \times k_{-1}$ (s^{-1})*	*t1/2*[a] *(s)*
Cockroach *Periplaneta americana*	0.024	1.33 ± 0.4	522 ± 130
Locust *Locusta migratoria*	0.3	2.57 ± 0.5	270 ± 55
Beetle *Adesmia* sp.	1.4	25.5 ± 7.5	30 ± 8.0
Moth larva *Spodoptera littoralis*	2.4	98.8 ± 20	7.2 ± 2.4
Beetle *Trachyderma philistina*	>10	76.3 ± 23	9.0 ± 2.8

[a]*t*1/2 is the time for half-dissociation calculated from the value of the dissociation constant according to $t1/2 = \ln(2/k_{-1})$ where k_{-1} is the dissociation constant (Benet, 1978).

Values are means ± SD ($N = 3$).

Biol.* *200* (7), 1115–1123.)

recombinant baculoviruses. An obvious enhancement of the insecticidal capacity was achieved by providing the *A. californica* multiple nuclear polyhedrosis baculovirus (AcMNPV), which infects various important lepidopterous pest insects, with the gene encoding AaIT (McCutchen *et al.*, 1991; Stewart *et al.*, 1991). This approach, with the AcMNPV-AaIT virus, has even yielded the first successful field trial of a genetically improved baculovirus (Cory, 1994). Besides the above *A. californica* (Ac-AaIT) recombinant baculovirus, the AaIT gene was used to design additional recombinant baculoviruses such as *Helicoverpa zea* NPV (Hz-AaIT) (Treacy *et al.*, 2000), which has revealed an insecticidal superiority over Ac-AaIT baculovirus on heliothine larvae in greenhouse and field trials. The HzNPV was considered to be a better vectoring agent (versus AcNPV) for designing recombinant clones targeted at multi-species heliothine insects. Similarly, a recombinant *Trichoplusia ni* nuclear polyhedrosis virus (TnNPV-AaIT) was designed in China and significantly shortened the time of killing of agronomically important insects. Furthermore, the mosquitocidal capacity of AaIT was demonstrated by infecting mosquitos with a recombinant AaIT expressing Sindbis virus. The mosquitocidal action of AaIT make it a potential candidate for inclusion in molecular recombinant methods of mosquito control (Higg *et al.*, 1995). Besides the excitatory AaIT toxin, the α insect specific LqhαIT was also expressed by a recombinant baculovirus AcNPV-LqhαIT, which has demonstrated an enhanced insecticidal potency against *H. armigera* larvae. Similarly, the AcNPV-LqhIT2 recombinant baculovirus expressing the depressant insect selective toxin was shown to be superior to the one expressing the AaIT toxin (Gershburg *et al.*, 1998). As indicated above (see Section 5.6.3.2.5) the double recombinant virus simultaneously expressing the excitatory and depressant toxins has demonstrated an insecticidal superiority over the single recombinant Ac baculovirus (Regev *et al.*, 2003). Apart from the scorpion venom derived excitatory and depressant insect selective toxins, a mite toxin (Tomalski and Miller, 1991), a sea anemone toxin, and a spider toxin (Krapcho *et al.*, 1995; Prikhodko *et al.*, 1996) were also employed for the construction of recombinant baculoviruses.

5.6.5.1.4. Baculoviral potentiation In contrast to the low and slow toxicity of the native toxin in lepidopterous larvae (Herrmann *et al.*, 1990), when these larvae are infected with a AaIT expressing recombinant baculovirus (such as BmNPV-AaIT), they show a reduction of survival time and the amount of host plant they damage when compared with the wild-type virus (Cory, 1994). The expressed toxin found in the circulation of the infected insects is chemically identical to the native toxin (Stewart *et al.*, 1991), mimics its symptoms of paralysis (Maeda, 1989), and requires a much lower hemolymph titer to induce a similar paralysis than the injected native toxin. The latter phenomenon, the enhanced activity of the expressed toxin, is designated as toxin potentiation and is demonstrated in **Table 7**.

Preliminary observations revealed that infection with the wild-type virus does not significantly affect the insect's susceptibility to injected native toxin. It was thus assumed that the above potentiation is a consequence of a pharmacokinetic-targeting cooperativity between the recombinant baculovirus and its expressed AaIT toxin. This hypothesis was most recently examined by toxicity assays, immunocytochemical microscopy, and electrophysiology, using silkworm larvae infected with wild-type BmNPV and the recombinant BmNPV-AaIT viruses.

Recent data (Elazar *et al.*, 2001) suggest that toxin potentiation is a consequence of its continuous expression in the virus infected tracheal epithelia, which ramify in the insect body. This, therefore, provides a local supply of freshly produced toxin, which translocates to the insect CNS thereby providing the expressed toxin with critical target sites inaccessible to the native toxin. This conclusion is supported

Table 7 Baculoviral potentiation; the concentration of the native and recombinant AaIT in the hemolymph of paralyzed lepidopterous larvae

Insect[a]	*Native toxin concentration (ng μl^{-1})*[b]	*Recombinant toxin concentration (ng μl^{-1})*[c]	*Potentiation*
H. virescens (tobacco budworm)	70[d]	1.0[e]	70
B. mori (silkworm)	45[f]	1.3[f]	35

[a]Fourth instar larvae were employed.
[b]The concentration of the native toxin was obtained by dividing the value of the paralytic dose (PD_{50}) and the hemolymph volume of lepidopterous larvae (Herrmann *et al.*, 1990).
[c]The concentration of the recombinant toxin in the hemolymph of the larvae infected by the recombinant baculoviruses (AcMNPV-AaIT; BmNPV-AaIT) was monitored by the blowfly larvae contraction paralysis assay (Zlotkin *et al.*, 1971a) on samples of hemolymph collected from the paralyzed larvae.

[e]From McCutchen *et al.* (1991).
[f]From Elazar *et al.* (2001).
Reproduced with permission from Elazar, M., Levi, R., Zlotkin, E., **2001.** Targeting of an expressed neurotoxin by its recombinant baculovirus. *J. Exp. Biol. 204* (15), 2637–2645.

by the data presented in **Figure 28**, which indicate that: (1) the recombinant AaIT toxin is expressed by a recombinant BmNPV AaIT virus in the tracheal epithelium of the tracheae, which are either enveloping or branching into the ventral nerve cord (VNC) (**Figure 28a**); (2) the tracheae surrounding the VNC are, in essence, an integral part of the protective sheath enveloping the insect's CNS; (3) as in **Figure 28b**, the high resolution immunogold method provides striking evidence for the presence of the recombinant AaIT deep inside the insect CNS; and (4) as in **Figure 28c**, the virus mediated presence of the recombinant toxin in the CNS has a functional significance. It reveals an obvious increase in the externally recorded spontaneous electrical activity in the VNCs derived from recombinant baculovirus (RBV) infected silkworm larvae when compared to wild-type baculovirus. The increase in the CNS derived electrical activity is correlated to the timing of the onset of paralysis in RBV infected larvae (data not shown).

The manner in which the virus localizes toxin delivery and toxin translocation is addressed by Engelhard *et al.* (1994), who examined the process of systemic host infection by the budded form of the baculovirus. The use of AcMNPV containing a *lacZ* reporter gene revealed that the major conduit for systemic viral infection, enabling its rapid spreading throughout the host insect, is through the tracheal system (Engelhard *et al.*, 1994), which is also accessible to external infection (Kirkpatrick *et al.*, 1994). The suitability of the tracheal system to guide the recombinant baculovirus and its expressed neurotoxin follows from the fact that the tracheal system is distributed among the various tissues, is intimately associated with individual cells, and is flexibly expanding and adapting itself to the growing organism by aid of the tracheoblasts (Engelhard *et al.*, 1994).

To summarize, toxin potentiation results from an interaction of the recombinant baculovirus with its expressed toxin, where the virus serves as a vector and provider of the toxin to the insect's nervous system via an existing and newly formed accessibility route, thereby producing CNS targeted neurotoxicity.

5.6.5.2. Cooperativity

5.6.5.2.1. The pharmacologic flexibility of the insect VGSC Presently, recombinant baculoviruses provide the most amenable system for the delivery of clonable insecticidal polypeptides for pest control purposes. A great deal of effort has been invested in the study of recombinant baculoviruses, and a number of cooperatively interacting combinations of substances is possible. Cooperative combinations can be delivered either as a cocktail of recombinant baculoviruses (O'Reilly *et al.*, 1992), each expressing separate insecticidal polypeptides, or the design of double recombinants, which express cooperative combinations of toxins in single virus preparations. A third possibility includes the combined delivery of recombinant baculoviruses with conventional organic insecticides.

The design of the above combinations is based on the so-called pharmacologic flexibility of the insect voltage-gated sodium channel (**Table 3**) as recently reviewed by Gordon (1997a), Gordon *et al.* (2002), and Zlotkin (1999), briefly:

The insect VGSC closely resembles its vertebrate counterpart in two major reaspects. First, in its structure and function and, second, in its pharmacological diversity and flexibility (**Table 3**). Despite their fundamental similarity, the most obvious pharmacologic distinction between the insect and mammal sodium channels is provided by the insect selective scorpion venom neurotoxins. However, the above toxins, when coupled to various binding (Moskowitz *et al.*, 1994) and toxicity (Herrmann *et al.*, 1995) assays have showed additional pharmacologic subdivisions among insect VGSCs. As presented in **Figure 17** the degree of displaceability between the excitatory and depressant toxins

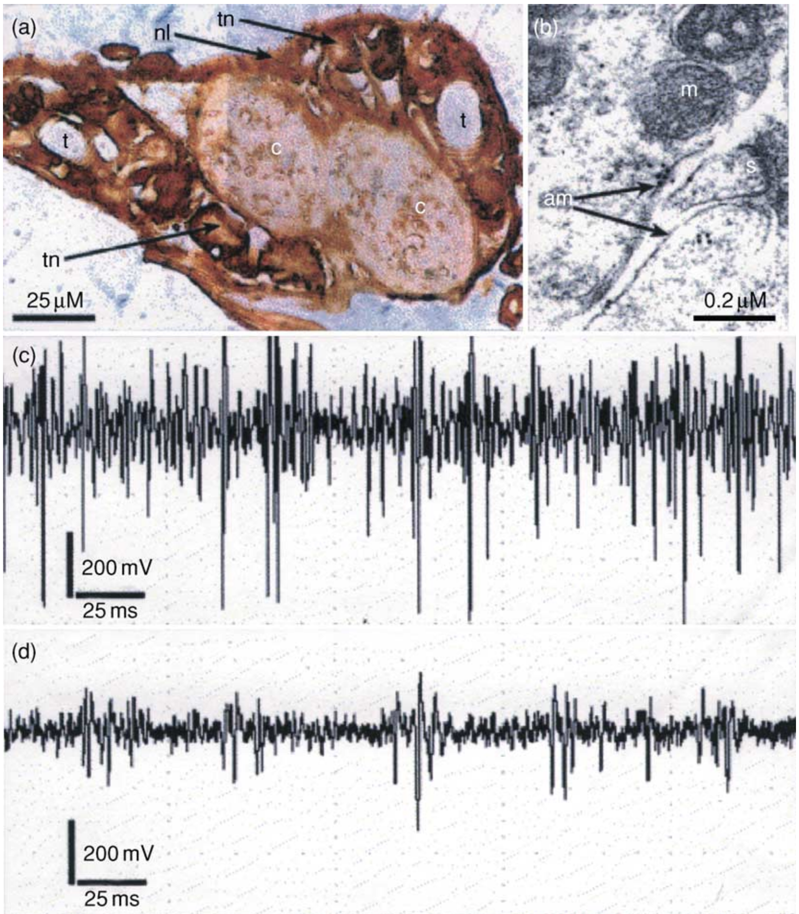

Figure 28 The expressed AaIT toxin is targeted by its recombinant baculovirus to the insect central nervous system (CNS). (a) Recombinant AaIT in the ventral nerve cord of silkworm larvae infected with BmNPV-AaIT. The expressed toxin is detected by anti-AaIT antibody and visualized by the horseradish peroxidase reaction (dark pigmentation, brown). The expressed AaIT is located in the cytoplasm of tracheal epithelial cells inside the neural lamella (nl) enveloping the two connectives (c) in close proximity to the abdominal ganglion. Note the hypertrophied tracheal epithelium with swollen nuclei (tn) and the cytoplasm loaded with the recombinant toxin. Scale bar = 25 μm. (b) Recombinant AaIT inside an abdominal ganglion of a silkworm larva infected with the above (a) recombinant baculovirus. The AaIT is detected by anti-AaIT antibody, visualized by gold-attached antibody and revealed by electron microscopy. AaIT is shown on axonal membranes (am, arrows) in the neuropil mass of the ganglion. Am, axonal membrane; c, connective; m, mitochondria; nl, neural lamella; s, synapse; t, trachea; tn, tracheal epithelium nuclei. Scale bar = 0.2 μm. (c, d) Spontaneous electrical activity recorded from VNC dissected from the 4th instar silkworm larvae 40–45 h following infection by the wild-type virus (WTBV) (d) and the recombinant, AaIT, expressing baculovirus (BmAaIT NPV) (c). Note the obvious difference in the intensity and frequency of the recorded responses from the infected ventral nerve cords. (Reproduced with permission from Elazar, M., Levi, R., Zlotkin, E., **2001**. Targeting of an expressed neurotoxin by its recombinant baculovirus. *J. Exp. Biol. 204* (15), 2637–2645.)

varies among various insect neuronal preparations (Moskowitz *et al*., 1994). Similarly, the positive cooperativity of insecticidal scorpion toxins varies among different test insects (Herrmann *et al*., 1995). Further, sodium channel subtyping was revealed by diverse toxins and neuronal preparations. For example, the binding of LqhαIT to locust neuronal membranes was cooperatively enhanced by veratridine due to increasing affinity and receptor site capacity (Gordon and Zlotkin, 1993). This is similar to the allosteric positive modulation that occurs between α toxins and veratridine (a plant lipophilic alkaloid; **Table 3**) in rat brain sodium channels. Alternatively, in contrast to negative modulation of α toxins in rat brain synaptosomes by brevetoxin (**Table 3**), brevetoxin was shown to increase the binding of LqhαIT to locusts' sodium channels (Cestele *et al*., 1995; Gordon, 1997a). Such differences indicate a structural/functional distinction between channel subtypes. The differential allosteric modulation may provide a new approach to increase selective activity of pesticides on target

organisms by the simultaneous application of allosterically interacting drugs (Gordon, 1997).

The allosteric modulation approach offers two forms of insecticidal interactions shown below: positive cooperativity and allosteric antagonism (or negative cross-resistance). In other words, the insect voltage-gated ion channel is targeted by two categories of insecticidal substances: industrial synthetic organic compounds and baculovirus mediated neurotoxic polypeptides. As shown below, they may be used in a cooperative fashion.

5.6.5.2.2. Positive cooperativity A recent examination of the insecticidal potency of various scorpion venom neurotoxins (Herrmann *et al.*, 1995) exemplifies this principle. It has been shown that a combination of two toxins increased the insecticidal activity five- to tenfold, with no apparent increase in mammalian toxicity. Synergistic combinations were obtained between toxins (such as AaIT and LqhαIT) that do not reveal competitive displaceability in binding assays and do not belong to the same site category. It is noteworthy that a similar cooperativity was demonstrated between the excitatory (AaIT) and depressant (LqIT2) toxins in their toxicity to lepidopterous larvae. These toxins do not displace each other in their binding to lepidopterous neuronal preparations (Moskowitz *et al.*, 1994), and they reveal an enhancement of recombinant baculovirus insecticidal efficacy against *H. virescens*, when simultaneously expressed by AcMNPV (see Section 5.6.3.2.4; Regev *et al.*, 2003). A second example of positive cooperativity is provided by a recent study (Gilles *et al.*, 2003), which reveals by the aid of binding studies (not toxicity assay on intact insects) that the binding affinity of LqhαIT toxin to locust CNS (but not to rat brain sodium channels) is allosterically increased by certain pyrethroids and brevetoxin-1 (**Figure 29**). Brevetoxin-1 also increases the binding of the excitatory AaIT (but not BjxtrIT) to insect sodium channels. This information is presented as an approach to tackle pyrethroid resistance by the aid of a combined use of synergistically acting insecticidal compounds (Gilles *et al.*, 2003, see also Section 5.6.5.2.1).

5.6.5.2.3. Allosteric antagonism (negative cross-resistance) An economically and environmentally more useful approach to resistance management is provided by the phenomenon defined as "negative cross-resistance," which is also designated as "allosteric antagonism." "Resistance" is officially defined by the World Health Organization as the "development of an ability in a strain of an organism to tolerate doses of toxicant, which would prove lethal

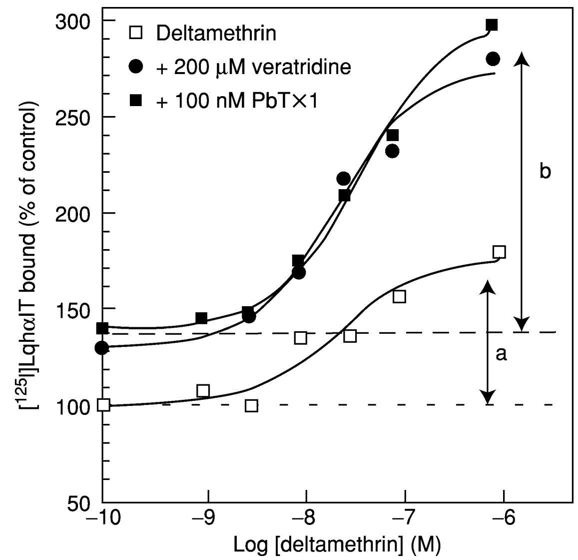

Figure 29 Effect of pyrethroids on LqhαIT binding to locust neuronal membranes. Synergic effect of deltamethrin on LqhαIT binding in the presence of saturating concentrations of deltamethrin alone (a) and together with 200 μM veratridine or 100 nM brevetoxin (PbTx-1) (b). Maximal specific binding of [^{125}I] LqhαIT alone (control 100%) and with veratridine or brevetoxin (without pyrethroid) are indicated by the lower and upper dashed lines, respectively. (Reproduced with permission from Gilles, N., Gurevitz, M., Gordon, D., **2003**. Allosteric interactions among pyrethroid, brevetoxin, and scorpion toxin receptors on insect sodium channels raise an attenative approach for insect control. *FEBS Lett. 540* (1–3), 81–85.)

to the majority of individuals in a normal (susceptible) population of the species" (Mullin and Jeffrey, 1992). Insecticide resistance, documented in almost all arthropod species in which it has been studied, is a major obstacle to the control of agriculturally and medically important pests (Hassall, 1990). Resistance can be acquired through the relatively rare behavioral or the more common physiological action. The physiological resistance may be subdivided into two main categories: the "metabolic" (modified permeability, excretion, detoxification-degradation) and the "altered target site" resistance. The knock-down resistance (KDR) phenomenon, which represents the most common form of resistance against DDT and pyrethroids, can be induced by various metabolic factors (Mullin and Jeffrey, 1992; Scott and Wheelock, 1992); but it is substantially attributed to an altered target site, namely, point mutations in the insect *para* type voltage-gated sodium channel (Taylor *et al.*, 1993; Williamson *et al.*, 1996; Dong, 1997; Pittendrigh *et al.*, 1997; Zlotkin *et al.*, 1999). As shown above, a similar pattern of resistance (namely, increased detoxification and modified target site) was revealed in the pre-existing tolerance of lepidopterous larvae and

certain tenebrionid beetles to the insect selective AaIT polypeptide (Herrmann *et al*., 1990; Fishman *et al*., 1997).

A reasonable possibility for insecticidal cooperativity is based on the assumption that if a certain population (or strain) of insects has developed through insecticidal-selective pressure, a modified voltage-gated ion channel, the presumed conformational change induced by the mutation can modify channel pharmacology. Such an assumption can be exemplified both by earlier and more recent findings that suggest the occurrence of an "allosteric antagonism" (negative cross-resistance) between the pyrethroid resistance phenomenon (knock-down resistance, KDR) and increased susceptibility to the insect sodium channel neurotoxicants. Such a phenomenon was previously observed in KDR houseflies and *N*-alkylamides (such as BTG 501–502). The latter were shown to be up to four times more effective against the super KDR strain (530) of houseflies (Elliot *et al*., 1986). It has also been shown (McCutchen *et al*., 1997) that neonate pyrethroid resistant (KDR) tobacco budworms exhibited a significantly reduced (by 33%) median lethal time (LT_{50}), when infected with a recombinant baculovirus expressing the AaIT toxin (AcAaIT) when compared with the wild-type budworms. Further, as shown in **Table 8**, KDR and super-KDR houseflies injected with the AaIT toxin revealed a 9- and 14-fold increase in their susceptibility to the AaIT toxin, respectively (Zlotkin *et al*., 1999). It is noteworthy that similar allosteric antagonism was shown by the acquisition of hypersensitivity to pyrethroids by TTX-resistant dorsal root ganglion sodium channels (Tatebayashi and Narahashi, 1994).

As discussed in Section 5.6.4.3, the AaIT toxin interacts with domain II of the insect VGSC at a receptor binding site that is different from those of the low molecular weight and lipophilic DDT and pyrethroids (Soderlund and Knipple, 1995). The latter presumably act at the intramembranous region of the channel, similarly to the lipid-soluble alkaloid gating modifiers, such as veratridine or batrachotoxin (Hille, 1992). With this background of binding site diversity, the data presented in **Table 8** demonstrate the pharmacological flexibility of sodium channels, which has implications for the management of insecticide resistance.

Briefly, the suitability of the insect sodium channel to serve as a target for future insecticides depends on: (1) its critical role in excitability (Hille, 1992); (2) its pharmacological diversity exhibited in the multiplicity of binding sites for various neurotoxicants, including four groups of industrial

Table 8 The paralytic effect (PD_{50}) of AaIT toxin to wild-type (WT) and pyrethroid-knockdown resistant (KDR) houseflies[a]

Housefly strain[b]	*PD_{50} (ng/insect ± SD)*[c]	*Susceptibility ratio*[d]
WT-"Cooper"	21.1 ± 1.35 (3)[e]	1.0
KDR[f]	2.3 ± 0.39 (3)	9.2
Super-KDR[g]	1.5 ± 0.25 (3)	14.0

[b]Bred in IACR, Rothamsted, UK.
[c]PD_{50} – paralytic dose 50%.
[d]Susceptibility ratio: PD_{50} of WT/PD_{50} of strain.
[e]Numbers in parentheses indicate the number of independent assays performed.
[f]KDR-stock 579 homozygous for a point mutation (L1014F) in the hydrophobic S6 transmembrane segment of homology domain II of the Para sodium channel, which confers resistance of about one order of magnitude to pyrethroid insecticides (Williamson *et al*., 1996).
[g]Super-KDR-stock 530, possessing two point mutations in the *para* gene: the first is the above KDR (L1014F) mutation. The second point mutation (M918T) is located in the intracellular loop, connecting segments 4 and 5 in homology domain II (Pittendrigh *et al*., 1997). The super-KDR strain is about 500-fold resistant to deltamethrin (Williamson *et al*., 1996; Pittendrigh *et al*., 1997).
Reproduced with permission from Zlotkin, E., **1999**. The insect voltage-gated sodium channel as target of insecticides. *Annu. Rev. Entomol. 44*, 429–455.

insecticides (**Table 3**); (3) it being pharmacologically distinguishable from vertebrate sodium channels as revealed by heterologous expression of the *Drosophila* Para sodium channel (Warmke *et al*., 1997) and the insect selectivity of neurotoxins derived from arachnid venoms; and (4) its pharmacological flexibility, as exhibited by the "allostereic antagonism" (**Tables 3 and 8**).

"Allosteric antagonism" indicates that binding of one ligand to the sodium channel protein induces a conformational change that affects its functionality and responsiveness to other toxicants acting at a different site on the channel protein (Soderlund and Knipple, 1995; Gordon, 1997a; **Table 3**). A similar conformational change in the channel protein could be induced by point mutations of the kind that confer insecticide resistance. Such a change may affect the responsiveness of the channel to various toxicants either by antagonizing or enhancing their effects. The decreased, as well as increased, susceptibilities to AaIT by the different sodium channel mutated fly strains (Zlotkin *et al*., 1999) provide evidence for such effects.

Finally, the above phenomenon of the allosteric antagonism (or negative cross-resistance) should be viewed against the background of the increasing agroeconomical significance of pyrethroid resis-

tance (Elliot *et al.*, 1986), and the appearance of bioinsecticides based on recombinant baculovirus expressing neurotoxins (Cory, 1994). These developments emphasize the need to clarify the molecular basis underlying the allosteric coupling between toxicant binding sites on the ion channel, in order to assess its implications for insecticide resistance management.

5.6.5.3. Oral Toxicity

The clonability of insect selective neurotoxic polypeptides and their availability to genetic manipulations, raises the possibility of employing them in the design of transgenic insect protected plants.

In order to exert their neurotoxic effectivity, the plant expressed polypeptide toxin has to cross the insect's digestive system in an intact, pharmacologically functional form. Some of the data mentioned below indicate that such a possibility is feasible.

A series of previous studies showed that the midgut of the blowfly *Sarcophaga falculata* is permeable to polypeptides, such as the amphipathic cobra venom cardiotoxin (Mr 7 kDa) (Primor and Zlotkin, 1978, 1980; Primor *et al.*, 1980; Fishman *et al.*, 1984) and the excitatory AaIT toxin (Zlotkin *et al.*, 1992). By the aid of a radioiodinated toxin ([^{125}I]-AaIT) it has been shown that about 0.5–2.0% of the orally fed toxin crosses the gut in an active-toxic form within 30–80 min. The gut crossing occurs through a certain, morphologically defined segment of the midgut (Fishman *et al.*, 1984; Zlotkin *et al.*, 1992). Since proteins such as the serum proteins (Nogge, 1971), immunoglobulins (Schlein *et al.*, 1976; Nogge and Giannetti, 1980), and horseradish peroxidase (HRP; Fishman and Zlotkin, 1984) were shown to readily cross the gut of *Sarcophaga* flies, the pesticidal significance of the above information is doubtful (Zlotkin *et al.*, 1992).

However, two recent reports indicate the feasibility of using insect protected transgenic plants. The first study reported on insect resistant transgenic plants engineered with insecticidal genes of venom neurotoxins, namely, tobacco plants expressing the AaIT neurotoxin (Yao *et al.*, 1996). Insect bioassays showed that some transgenic plants had notable insect resistant activity. A similar result was obtained with *Agrobacterium tumefaciens* mediated transformation of rice with a spider insecticidal gene, conferring resistance to the leaf borer and the striped stem borer (Huang *et al.*, 2001). Insect bioassays demonstrated that the transgenic plants had an enhanced resistance to these pests. These encouraging results suggest that the digestive system of lepidopterous insect pests is permeable to insecticidal polypeptides. Such a conclusion is supported by a second recent report (Fishman *et al.*, 2003), which revealed that adult *Spodoptera* noctuid moths respond by paralysis within 10–30 min when given an orally delivered solution of crude scorpion venom. When the same venom is delivered by injection, a similar but faster paralysis occurs at a roughly 30 times lower dosage. The orally induced paralysis is noticeably enhanced by the addition of proteolytic blockers to the ingested toxic solutions. It appears that the moth's gut is permeable to polypeptides and the degree of the oral toxicity is determined by the proteolytic activity in the gut lumen. The above considerations can serve as guidelines for the study and design of gut permeable, insect selective neurotoxic polypeptides.

5.6.6. Concluding Remarks

This article focuses on the insect selective neurotoxic polypeptides derived from buthid scorpion venoms that affect voltage-gated sodium channels. The topic is treated from ecological, pharmacological, structural–molecular, and applicative points of view. A question that may be asked is what is the lesson provided by the insect selective toxins? Four possible answers are offered to this question:

1. From an ecological-evolutionary point of view one is impressed by the diversity in the composition of scorpion venom, strongly contrasting with the conservation of their morphology and anatomy (living fossils). It would appear that the selective pressure is mainly directed to and absorbed by the venom gland, which is an essential instrument for their survival (Zlotkin, 1983). The diversity and multiplicity of the phyletic toxins can be explained on the basis of an assumption that natural selection coevolved distinct types of ion channels in various groups of animals at the same time as the scorpions evolved specific peptide toxins that are aimed to affect the normal function of these ion channels for the purpose of prey capture or defense from predators (Possani *et al.*, 1999).
2. From a strictly neuropharmacological point of view, the insect selective toxins reveal the structural/functional uniqueness of the insect voltage-gated sodium channel, and serve as probes and pharmacological tools for the study of its chemistry and functional significance. In fact, these toxins provided the first clear indication for the occurrence of pharmacologically

distinguishable ion channel subtypes (Zlotkin *et al*., 2000).

3. As an exercise in the functional anatomy of neurotoxic polypeptides, the scorpion toxins provide a model for the design of useful polypeptides. They possess the appropriate balance between structural rigidity (provided by the peptidic backbone of the toxin molecule or its conserved "scaffold") and flexibility (provided by the "variable loops" and their aliphatic chains, such as arginine and lysine amino acids, which possess the respective functional guanidinium and amino groups). Thus, in scorpion toxins, the basic residues connected to the scaffold serve as multipoint interaction sites with the target molecules (Loret and Hammock, 2001). The above positively charged and hydrophobic residues form the bioactive surface.
4. The agronomical-applicative aspect serves as the main lesson of these insect selective toxins. It suggests a technological combination between the structural modifiability of the polypeptide insect selective neurotoxins and the pharmacological (allosteric) flexibility of the insect voltage-gated sodium channels. Such combination may enable the design of an insecticidal-resistance management strategy, based on synergistic or negative cross-resistance coupling among neurotoxins or among neurotoxins and classical organic insecticides. It also encourages the development of new modes for the delivery of the clonable and modifiable insect selective neurotoxins.

Acknowledgments

The topic of scorpion neurotoxins was recently presented and discussed in a series of review articles to which the reader is referred: Simard and Watt (1990), Martin-Eauclaire and Couraud (1995), Gordon *et al*. (1998), Zlotkin (1999), Possani *et al*. (2000), Zlotkin *et al*. (2000). The following recent text books provide an additional perfect source of updated information on the subcellular-molecular level: Bon (2000) and Menez (2002). However, in preparing the present review the following articles were especially useful by providing comprehensive and well-designed overviews on the neuropharmacology (Gordon *et al*., 2002), chemistry (Possani *et al*., 1999), structure–function (Gurevitz *et al*., 2002), and applicability (Loret and Hammock, 2001) of scorpion neurotoxins-affecting voltage-gated sodium channels.

Reported studies conducted by the author were supported by US-Israel BSF and BARD foundations as well as the Ciba-Geigy Company.

5.7 Spider Toxins and their Potential for Insect Control

F Maggio, B L Sollod, H W Tedford, and G F King, University of Connecticut Health Center, Farmington, CT, USA

5.7.1. Introduction

Insects are the most diverse and successful animals on the planet, with the number of extant species estimated to be ~5 million (Novotny *et al*., 2002). However, the ability of insects to inhabit a wide variety of ecological niches has inevitably brought them into conflict with humans. Although only a small minority of insects are classified as pests, they nevertheless destroy 20–30% of the world's food supply (Oerke, 1994) and transmit a diverse array of human and animal pathogens.

In terms of agronomic importance, lepidopterans are the most pernicious insects, with ~40% of all chemical insecticides directed against heliothine species (Brooks and Hines, 1999). However, from a global human health perspective, mosquitoes are the most problematic arthropods, being responsible for the transmission of malaria, filariasis, and numerous arboviruses. Although malaria is unquestionably the most devastating insect-borne disease, causing an estimated 2 million deaths per year (Gubler, 1998), the increasing incidence of epidemics caused by mosquito-borne arboviruses (e.g., dengue, West Nile, Japanese encephalitis, yellow fever, and Rift Valley fever) is a mounting public health issue (Gubler, 2002). Other insects of significant public health importance include sandflies, tsetse flies, fleas, and triatomid bugs, which transmit the causative agents of leishmaniasis, trypanosomiasis (African sleeping sickness), plague, and Chagas disease, respectively (Gubler, 1998; Gratz, 1999).

5.7.2. Chemical Control of Insect Pests

Humans have been engaged in internecine chemical warfare with insects ever since Paris Green (copper acetoarsenite) was introduced as an insecticide by French grape growers in the 1870s (Winston, 1997; Dent, 2000). However, our chemical assault on insects dramatically intensified with the introduction of dichlorodiphenyltrichloroethane (DDT), the first synthetic organic pesticide, during World War II (Casida and Quistad, 1998). DDT was effective not only in the agricultural sector, but formed the basis of initially successful malaria eradication programs (Attaran *et al*., 2000). The subsequent introduction of organophosphate and carbamate insecticides in the 1960s (Casida and Quistad, 1998) encouraged the prevailing view that chemical insecticides would prove to be a universal remedy for the control of insect pests.

This optimistic outlook was unwarranted for several reasons. First, chemical control subjects the insect population to Darwinian selection and the development of resistance is as inevitable as the evolution of bacterial resistance to overprescribed antibiotics. Moreover, the fact that the vast majority of

insecticides act on one of just four nervous system targets – the voltage-gated sodium channel, the nicotinic acetylcholine receptor (nAChR), the γ-aminobutyric acid (GABA)-gated chloride channel, and acetylcholinesterase – promoted the development of cross-resistance to different families of insecticides (Brogdon and McAllister, 1998). As of 1992, more than 500 species of insects and mites, including 56 anopheline and 39 culicine mosquitoes, had developed resistance to one or more classes of insecticides (Feyereisen, 1995; Brogdon and McAllister, 1998). Second, most chemical insecticides are relatively broad-spectrum, and indiscriminate use can lead to catastrophic environmental, ecological, and human health-related problems. Because these chemicals kill nontarget arthropods, including natural enemies of the targeted pest, there are several instances where insecticide application has exacerbated rather than ameliorated the targeted insect-pest problem (Winston, 1997; Dent, 2000).

The publication in 1962 of Rachel Carson's landmark book *Silent Spring* (Carson, 1962) substantially raised public awareness of the potential adverse impacts of synthetic insecticides and ultimately led to a paradigm shift in the development and use of these chemicals. Deregistration of DDT and other organochlorines in the 1970s in the USA stimulated the agrochemical industry to develop a new generation of insecticides that have increased biological activity (leading to reduced application rates/amounts), enhanced specificity, reduced environmental persistence, and decreased mammalian toxicity (Dent, 2000). Nevertheless, several classes of widely used insecticides will soon be lost from the marketplace due to either resistance development or deregistration by regulatory authorities following retrospective review. Combined with more demanding registration requirements for new agrochemicals, this is likely to decrease the pool of effective chemical insecticides in the near future (Rose, 2001; Zaim and Guillet, 2002). Thus, there is a pressing need to isolate safe insecticidal compounds and to develop viable alternatives to chemical insecticides. In this chapter, the potential of natural insecticidal toxins derived from spider venoms to fuel developments in each of these areas will be reviewed.

5.7.3. Spiders and Their Venoms: A Brief Overview

Excluding insects, which are their primary prey, spiders are the most successful terrestrial invertebrates (Rash and Hodgson, 2002). There are about 38 000 described species (Platnick, 1997), with at least a similar number undescribed. The vast majority belong to the two major suborders Araneomorphae and Mygalomorphae. Araneomorphs (modern spiders) represent ~90% of the world's spiders. The primitive spiders, or mygalomorphs, use their silk in a rudimentary manner compared to modern web-weavers and they prey primarily on nonflying arthropods. This suborder includes most of the large spiders that have inspired popular myths and Hollywood movies, including the tarantulas (theraphosids) and trapdoors, which are both harmless to humans (Escoubas and Rash, 2004; Isbister and White, 2004), and the highly venomous Australian funnel-web spiders (Nicholson and Graudins, 2002; Isbister and White, 2004).

As for other venomous creatures, such as scorpions and cone snails, the venoms of most spiders are a heterogeneous mixture of inorganic salts, low molecular mass organic molecules (<1 kDa), small linear peptides (typically 2–4 kDa), disulfide-reticulated polypeptides (typically 3–8 kDa), and high molecular mass proteins including enzymes (>10 kDa) (Escoubas *et al.*, 2000; Gomez *et al.*, 2002; Rash and Hodgson, 2002; Kuhn-Nentwig *et al.*, 2004; Tedford *et al.*, 2004). These complex chemical cocktails have evolved for the primary purpose of killing or paralyzing arthropod prey, although some compounds may play an additional role in predigestion of the injected victim (Rash and Hodgson, 2002). In the following sections, a brief overview of the insecticidal peptide and polyamine components that have been isolated from spider venoms are provided.

5.7.4. Insecticidal Acylpolyamine Toxins from Spider Venom

Polyamine toxins are low molecular weight secondary metabolites found in the venom glands of spiders and wasps (Strømgaard *et al.*, 2001). They appear to be a common component of both araneomorph (Aramaki *et al.*, 1986; Grishin *et al.*, 1989; Quistad *et al.*, 1991) and mygalomorph (Fish-Fisher and Bohn, 1957; Gilbo and Coles, 1964; Skinner *et al.*, 1990) venoms, where their primary function is to induce rapid paralysis of envenomated prey. Although first identified in spider venoms more than 40 years ago, they were not structurally and functionally characterized until the mid-1980s (Strømgaard *et al.*, 2001; Rash and Hodgson, 2002; Mellor and Usherwood, 2004).

Acylpolyamine toxins typically contain an unbranched polyamine chain composed of two to four secondary amino groups separated from each

other by two to eight methylene groups (Strømgaard *et al*., 2001). One end of the chain usually terminates with a primary amino or guanidino group, while an aromatic moiety (such as a 2,4-dihydroxyphenylacetyl group or an indol-3-acetyl group) is typically attached to the other end via an amide bond (**Figure 1a**). Polyamine toxins are capable of low affinity, nonspecific interactions with a variety of proteins, and as such their pharmacology is complex and not amenable to description with a few generalizations. Although some polyamine toxins from wasp venom antagonize nAChRs, and argiotoxin-636 from the orb-weaving spider *Argiope lobata* inhibits voltage-gated Na^+ and K^+ currents in vertebrate neurons, these toxins are thought to have evolved primarily as antagonists of arthropod ionotropic glutamate receptors (Strømgaard *et al*., 2001; Mellor and Usherwood, 2004). While these toxins have proved to be valuable pharmacological tools, they have never been seriously exploited as insecticide leads, possibly due to undesirable characteristics such as poor phyletic specificity, undesirable pharmacokinetics, and difficulties with synthesis and purification (Strømgaard *et al*., 2001). However, none of these characteristics absolutely rules out a possible success for insecticide discovery strategies that

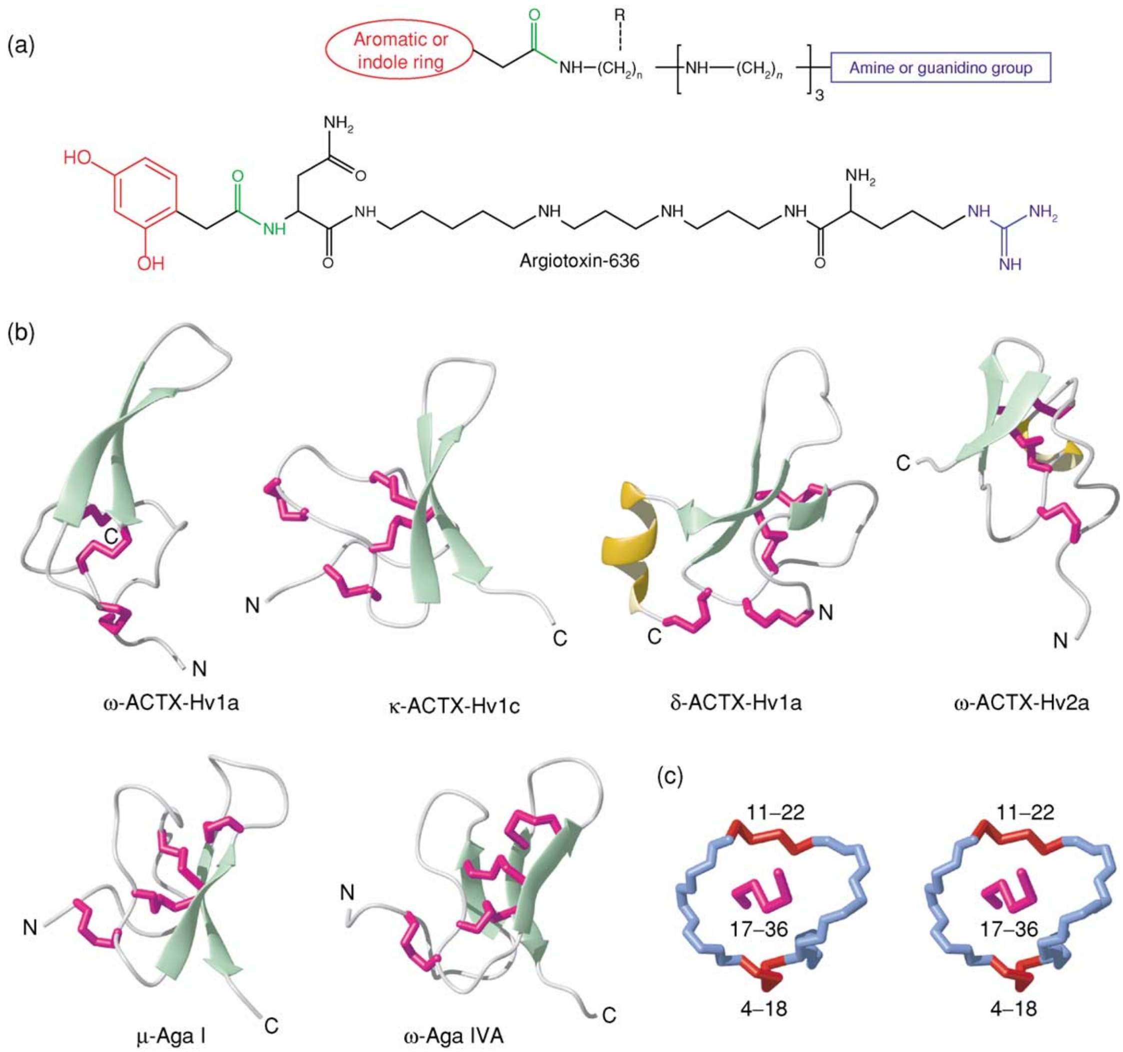

Figure 1 (a) The structure of argiotoxin-636 from the orb-weaving spider *Argiope lobata* below a generalized outline of the structure of spider venom acylpolyamines. (b) Schematic representations of the three-dimensional structure of the only six insecticidal spider toxins whose tertiary structure has been determined. The atracotoxins (ACTX) are from the Australian funnel-web spider *Hadroncyhe versuta* and the agatoxins (Aga) are from the unrelated American funnel-web spider *Agelenopsis aperta*. The β strands and α helices are shown in green and orange, respectively, and disulfide bridges are drawn as magenta tubes. The N- and C-termini of each toxin are labeled. Protein Data Bank accession codes are given in **Table 1**. (c) Stereo view of the cystine knot motif of ω-ACTX-Hv1a. The Cys17–Cys36 disulfide bond (magenta) is threaded through a closed loop formed by the Cys4–Cys18 and Cys11–Cys22 disulfide bridges (red) and the intervening sections of polypeptide backbone (blue).

exploit acylpolyamines either as rational design templates or as tracers in competitive ligand binding assays.

5.7.5. Insecticidal Peptide Toxins from Spider Venom

5.7.5.1. Spider Venom Polypeptides: An Underexploited Pharmacological Reservoir

Peptide toxins are expressed in the venom gland of spiders in a combinatorial fashion, and hence they tend to be the principal venom constituents (Escoubas *et al*., 2000; Escoubas and Rash, 2004; Kuhn-Nentwig *et al*., 2004; Tedford *et al*., 2004) (see Section 5.7.5.2). However, few spider venoms have been studied in sufficient detail to enable the extent and diversity of these peptidic components to be reliably estimated. A recent mass spectrometric analysis of 55 different tarantula venoms led to a conservative estimate of ~50 peptides per venom (Escoubas and Rash, 2004), and a similar level of peptide diversity has been reported in the venoms of the primitive hunting spider *Plectreurys tristis* (Quistad and Skinner, 1994), the Australian funnel-web spider *Hadronyche versuta* (Wang *et al*., 1999; Tedford *et al*., 2004), and the Central American wandering spider *Cupiennius salei* (Kuhn-Nentwig *et al*., 2004). If one assumes a total of ~80 000 spider species, then a conservative estimate of 20 pharmacologically distinct peptides per species leads to an estimated total of ~1.5 million spider venom polypeptides, which is a much larger pharmacological repertoire than the 50 000–100 000 peptides estimated to be present in the venoms of cone snails (Olivera and Cruz, 2001) and scorpions (Possani *et al*., 1999). It was recently estimated, based on available journal and patent literature, that <0.01% of the pharmacological diversity of spider venoms has been tapped thus far (Tedford *et al*., 2004).

Apart from studies of acylpolyamines, most early investigations of spider venoms focused on isolation of polypeptides with vertebrate neurotoxic activity. Some of these peptides, such as the ω-agatoxins (Olivera *et al*., 1994), have become invaluable tools in vertebrate pharmacology because of their selectivity for specific subtypes of vertebrate voltage-gated ion channels. Although genes encoding these peptides might be suitable for engineering recombinant insect viruses (see Section 5.7.6), their broad-spectrum toxicity makes them unsuitable as leads for chemical insecticides. However, the overwhelming majority of spiders are harmless to humans (Isbister and White, 2004), and therefore it is not surprising that appropriately designed venom screens have led to the discovery of insect-specific spider venom polypeptides (Skinner *et al*., 1992; Krapcho *et al*., 1995a, 1995b, 1997; Fletcher *et al*., 1997b; Johnson and Kral, 1997; Johnson *et al*., 1997, 1998; Atkinson *et al*., 1998; Balaji *et al*., 2000; Corzo *et al*., 2000; Wang *et al*., 2000, 2001; de Figueiredo *et al*., 2001; Lipkin *et al*., 2002; Zhang *et al*., 2003).

5.7.5.2. Expression and Evolution of Spider Venom Polypeptides: Rolling the Dice

Toxic polypeptides are found in the venoms of numerous animals, including scorpions, snakes, and cone snails, as well as the nematocysts of sea anemones. While these peptides are invariably expressed as longer precursors that are posttranslationally processed to yield the mature toxin, the nature of the precursor depends on the animal. In the aquatic cone snails and sea anemones, toxic polypeptides are initially translated as prepropeptides that are posttranslationally processed to yield the mature toxin (Olivera *et al*., 1999; Anderluh *et al*., 2000). In contrast, the precursors of most peptide toxins from snakes and scorpions lack a propeptide region (Goudet *et al*., 2002; Fujimi *et al*., 2003). Araneomorph and mygalomorph spiders generally conform to the prepropeptide paradigm (Wang *et al*., 2001; Gomez *et al*., 2002; Corzo *et al*., 2003). The precursor typically comprises an N-terminal signal sequence (16–25 residues) followed by a propeptide region of highly variable length (13–58 residues) which precedes a single downstream copy of the mature toxin sequence. For reasons that have yet to be determined, the propeptide region of most spider toxin precursors is rich in acidic residues (Santos *et al*., 1992; Diniz *et al*., 1993; Krapcho *et al*., 1995b; Wang *et al*., 2001; Liang, 2004; Ostrow *et al*., 2003).

Spider toxins are typically not produced as "one-offs." Rather, each toxin is generally expressed in the form of a small library of variants that can differ significantly or by as little as one amino acid in the mature toxin sequence (Skinner *et al*., 1989, 1992; Stapleton *et al*., 1990; Quistad and Skinner, 1994; Krapcho *et al*., 1995b; Sanguinetti *et al*., 1997; Johnson *et al*., 1998; Kalapothakis *et al*., 1998; Wang *et al*., 1999, 2000; Corzo *et al*., 2000, 2003; Lipkin *et al*., 2002; Kuhn-Nentwig *et al*., 2004; Liang, 2004). Recent comprehensive analyses of venom gland cDNA libraries from several species of Australian funnel-web spider indicate that a single species typically expresses three to ten variants of each peptide toxin (Sollod *et al*., 2003). Interspecies comparisons reveal that the mature toxin region has been poorly conserved during speciation whereas the signal sequences of the variants are nearly identical. This dichotomy

between a highly conserved signal sequence and highly variable mature toxin sequence suggests that spiders, like cone snails (Duda and Palumbi, 1999; Olivera *et al.*, 1999; Conticello *et al.*, 2001), have diversified their toxin pool by developing a mechanism for accelerated evolution (hypermutation) of the mature toxin region relative to the signal sequence. Remarkably, the cysteine residues, which are critical for determining the tertiary structure of the toxins, are strictly conserved within the otherwise hypervariable mature toxin region.

Thus, spiders are master combinatorial chemists; for hundreds of millions of years they have been synthesizing combinatorial peptide libraries using various cystine frameworks as a structural scaffold. Hypermutation of the mature toxin sequence has facilitated the evolution and optimization of toxins with new functionalities, while maintenance in the venom of a minilibrary of toxin variants presumably enables the spider to target slightly altered versions of the same receptor in different insects, or even differentially edited/spliced versions of the same receptor within a single insect.

5.7.5.3. Three-Dimensional Structure of Spider Venom Polypeptides: A Tale of Ropes and Knots

While it is difficult to make structural generalizations about spider venom polypeptides based on the small number of toxins that have been studied, some trends are apparent. The peptides that have been isolated thus far can be grouped into three categories:

1. Linear amphipathic peptides, typically of mass 2–4 kDa, with no disulfide bonds.
2. Medium-sized neurotoxic peptides, typically of mass 3–6 kDa and reticulated with three to five disulfide bonds.
3. Larger polypeptides (6–9 kDa) with four or more disulfide bonds.

There are few characterizations of the highly reticulated peptides with mass >6 kDa, and no three-dimensional structures have been determined for any member of this group. An extensive mass spectrometric analysis of 55 tarantula venoms (see figure 2b in Escoubas and Rash, 2004), as well as less detailed mass spectrometric analyses of Australian funnel-web spiders (Wang, 2000; Wilson, Wilson, 2001), suggests that the medium-sized neurotoxic peptides predominate in mygalomorph venoms. However, venom from the araneomorph *C. salei* appears to be markedly different: small amphipathic peptides appear to be the principal constituents of this venom, which also contains a higher proportion of high-mass peptides and less of the medium-sized neurotoxic peptides than mygalomorph venoms (Kuhn-Nentwig *et al.*, 2004).

The small linear peptides expressed in spider venoms have antimicrobial activity and in this respect they are similar to the cecropin-like peptides that are found in the hemolymph of numerous arthropods, where they form part of the innate immune system that protects against invasion by pathogenic organisms (Boman, 2003). However, the peptides found in the venoms of spiders and other invertebrates, including bees, wasps, ants, and scorpions, differ from the cecropins in that their antimicrobial activity appears to be a consequence of relatively nonspecific cytolytic activity against prokaryotic and eukaryotic cells. While these peptides appear to form amphipathic α helices in membrane-mimetic solvents or when bound to biological membranes, they exist in flexible "rope-like" conformations in the absence of lipid bilayers (Corzo *et al.*, 2001, 2002; Kuhn-Nentwig *et al.*, 2004). Some of these peptides are neurotoxic to insects, but their primary function appears to be to synergize the neurotoxic activity of the larger disulfide-reticulated peptides by optimizing their access to the insect nervous system (Corzo *et al.*, 2002; Kuhn-Nentwig, 2003; Kuhn-Nentwig *et al.*, 2004). The broad-spectrum activity of the linear cytolytic peptides makes them unsuitable as insecticide leads, although it has been suggested that genes encoding these toxins might synergize with neurotoxin transgenes in enhancing the efficacy of insect-specific viruses (Corzo *et al.*, 2002; Kuhn-Nentwig, 2003).

The majority of insect-specific toxins isolated from spider venom are medium-sized neurotoxic polypeptides (typically 30–50 amino acid residues) with three to five disulfide bonds (summarized in **Table 1**). Most of these toxins act presynaptically at insect neuromuscular junctions, either by enhancing or inhibiting neurotransmitter release, although several act at sites within the insect central nervous system (Johnson *et al.*, 1998; Bloomquist, 2003; Tedford *et al.*, 2004). Three-dimensional structures have been determined for six of these toxins (**Figure 1b**), and they all contain a structural motif known as the inhibitor cystine knot (ICK) (Pallaghy *et al.*, 1994; Norton and Pallaghy, 1998; Craik *et al.*, 2001). The cystine knot comprises a ring formed by two disulfides and the intervening sections of polypeptide backbone, with a third disulfide piercing the ring to create a pseudo-knot (see **Figure 1c**). Except for the special case of cyclic ICK peptides, cystine knots are not true topological knots since, at least theoretically, they can be untied by a nonbond-breaking geometrical transformation (Craik *et al.*, 2001). Nevertheless, the cystine knot

Table 1 Overview of neurotoxic insecticidal peptides isolated from spider venom

[a]If a venom contains several variants of a toxin, only the protoypic family member is listed.
[b]Abbreviations used: VGSC, voltage-gated sodium channel; VGCC, voltage-gated calcium channel; CNS, central nervous system.
[c]The Protein Data Bank accession number is given for toxins whose three-dimensional structure has been determined.
[d]*Agelenopsis aperta* contains several variants of this toxin (μ-Aga II to VI) (Skinner *et al.*, 1989). Similar toxins are found in the venom of the related American funnel-web spider *Hololena curta* (Stapleton *et al.*, 1990) and *Paracoeletes luctuosus* (Corzo *et al.*, 2000). Some of these toxins appear to be insect-selective, while others are neurotoxic to mice (Corzo *et al.*, 2000).

[e]This toxin is a heterodimer in which 66- and 3-residue peptides are linked by an intermolecular disulfide bond (Santos *et al.*, 1992).
[f]This 11 kDa toxin has never been fully sequenced (Adams *et al.*, 1990).
[g]Tedford *et al.* (2001, 2004).
[h]Maggio and King (2002).
[i]A similar toxin (Magi 4) is found in the venom of *Macrotheles gigas* (Corzo *et al.*, 2003).
[j]The C-terminal Thr residue in PLTX-II is amidated and *O*-palmitoylated (Branton *et al.*, 1993).
[k]A toxin with similar N-terminal sequence was isolated from *Segestria* sp. many years earlier and shown to be insect-selective, but the complete amino acid sequence was not reported (Johnson and Kral, 1997).
[l]Reclassified as *Ornithoctonus huwena* (Wang) in a recent taxonomic revision.

provides peptidic neurotoxins with tremendous stability and resistance to proteases, thereby ensuring that the injected toxin is not degraded before reaching its nervous system target.

5.7.6. Toxin-Based Target Validation and Screening

Surprisingly, the molecular target of about 50% of the neurotoxins listed in **Table 1** has not been determined. However, it is striking that all spider venom-derived peptide neurotoxins with known molecular targets are directed against ion channels. Ion channels are well-validated insecticide targets (Bloomquist, 1996), with the vast majority of synthetic insecticides acting on voltage-gated sodium channels (the target of DDT, pyrethroids, oxadiazines, dihydropyrazoles, veratrum alkaloids, and *N*-alkylamides), nicotinic acetylcholine receptors (the target of neonicotinoids and spinosyns), or GABA/glutamate-gated chloride channels (the target of dieldrin, lindane, endosulfan, avermectins, and phenylpyrazoles). Of the major insecticide classes, only the organophosphate and carbamate insecticides (which target acetylcholinesterase) are not directed against this group of ligand- and voltage-gated ion channels.

Clearly, in order to minimize the potential for cross-resistance, it would be highly advantageous for new insecticides to act on targets outside of this established ion channel triumvirate. While the majority of well-characterized spider toxins appear to act on voltage-gated sodium channels (VGSCs), the overutilization of this target makes these toxins the least interesting in terms of developing high-throughput screens (HTSs) for small-molecule insecticide leads. It should be noted, however, that at least some of these toxins (e.g., δ-ACTX-Hv1a (Nicholson *et al*., 1996) and Magi 2, 3, and 5 (Corzo *et al*., 2003)) bind VGSCs at sites distinct from current-generation insecticides. Thus, the high penetrance in many insect populations of alleles conferring resistance to certain VGSC insecticides may not compromise newly developed chemical control agents that utilize different sodium channel binding sites (Bloomquist, 1996). In fact, insects with these resistance alleles might have increased susceptibility to such chemicals since insects with pyrethroid-resistance alleles are significantly more susceptible to both *N*-alkylamides and scorpion toxins that bind VGSCs at sites different from the pyrethroids (Zlotkin *et al*., 2000).

It is apparent from **Table 1** that many of the most potent spider venom toxins target neuronal voltage-gated calcium channels (VGCCs). This is not particularly surprising since insect VGCCs play a critical role in modulating cellular excitability and neurotransmitter release, and severe loss-of-function mutations in *Drosophila melanogaster* genes encoding the pore-forming α_1 subunits of both the L-type (*Dmca1D*) and P/Q/N-type (*Dmca1A*) VGCCs are embryonic lethal (Eberl *et al*., 1998; Smith *et al*., 1998; Kawasaki *et al*., 2002) (note that the designation of L- and P/Q/N-type channels is based solely on gene homologies with vertebrate VGCCs, not electrophysiological or pharmacological criteria). It is therefore remarkable that no commercial insecticides have ever been targeted against VGCCs. The lack of phyletic specificity of the ω-agatoxins possibly encouraged the misconception that insect VGCCs could not be selectively targeted. However, the highly insect-selective ω-atracotoxins (King *et al*., 2002; Tedford *et al*., 2004) demonstrate that such specificity is indeed possible. Hence, as suggested previously (Hall *et al*., 1994), insect VGCCs appear to be excellent HTS targets. The major impediment to implementing such HTSs will be development of heterologous expression systems for the relevant insect VGCCs. Thus far, there are no examples in the scientific or patent literature of heterologous expression of a functional arthropod VGCC.

An exciting recent development is the observation that the κ-atracotoxins (previously known as the Janus-faced atracotoxins) (Wang *et al*., 2000; King *et al*., 2002; Maggio and King, 2002) are selective for insect K^+ channels (Tedford *et al*., 2004). As far as we are aware, no synthetic chemical insecticides have ever been developed that target K^+ channels. Isolation of a lethal invertebrate-specific K^+ channel blocker was somewhat unexpected, since all loss-of-function K^+ channel alleles in *Drosophila* are viable (Wicher *et al*., 2001). Nevertheless, induction of a κ-ACTX-Hv1c transgene in *D. melanogaster* for just 10–15 min induces a lethal phenotype (Maggio, King, and Reenan, unpublished data), which strongly validates this ion channel as a viable insecticide target. In contrast with insect VGCCs, heterologous expression systems are available for numerous invertebrate K^+ channels (Wicher *et al*., 2001), and many HTS formats have been developed for K^+ channel targets (Kirsch *et al*., 2001; Ford *et al*., 2002).

An important consideration in implementing high-throughput insecticide screens with these ion channels is that one would like to mimic the phyletic specificity as well as the potency of the toxin used to validate the target. This contrasts with pharmaceutical development, where one can simply look for potent channel blockers (or activators) without regard for phyletic specificity. Ion channels are typically highly promiscuous with respect to available binding

sites, as exemplified by VGSCs which display at least nine topologically distinct binding sites for toxins and insecticides (Zlotkin *et al*., 2000). Thus, a screen designed to simply select for potent channel blockers has a high probability of yielding phyletically indiscriminate lead compounds that bind the channel at a location distinct from the binding site for the toxin used to validate the target. The probability of selecting lead compounds that are insect-selective is likely to be significantly increased if the primary screen is developed to identify molecules that compete with the toxin for its specific channel binding site; alternatively, a noncompetitive primary screen could be followed by a secondary screen that selects for such competitors.

5.7.7. Toxin-Based Bioinsecticides: A New Era of Biological Control

5.7.7.1. A Brief History of Conventional Biological Control Methods

Biological control methods were introduced well before the advent of synthetic insecticides, and in many instances were extremely successful. Indeed, the first use of biological control in North America was a spectacular success (Caltagirone and Doutt, 1989; Winston, 1997). In the 1880s, a massive outbreak of the accidentally introduced cottony-cushion scale (*Icerya purchasi*) threatened to decimate the infant Californian citrus industry. Over the winter of 1888–89, at a cost of only $1500, the US Department of Agriculture released the Australian ladybird beetle, *Rodolia cardinalis*, a voracious and specific predator of the cottony-cushion scale. Within a matter of months, the problematic scale was completely controlled within the introduced areas. Unfortunately, the introduction of broad-spectrum synthetic insecticides in the 1940s substantially diminished the success rate in subsequent predator/parasite release programs, largely because the introduced predators and parasites were just as susceptible to insecticides as the targeted pest insect. Ironically, cottony-cushion scale reappeared as a problem in California in the 1940s when citrus growers began experimenting with DDT and other insecticides that failed to discriminate between *Rodolia* and scale insects (Winston, 1997).

Another biological control method that has been used with variable success is the release of sterile insects. In this approach, male insects are sterilized, usually by irradiation, and released in large excess over the native male population. A textbook case was the total eradication of screwworm, a major pest of goats, from the Venezuelan island of Curaçao in the 1950s (Winston, 1997). However, Curaçao is small and well separated from the mainland and neighbouring islands, and very few sterile insect release (SIR) programs have worked when applied to less ecologically isolated areas. In part, this is because the cost of traditional SIR programs are astronomical compared with predator release programs due to the massive rearing facilities that need to be built and maintained to enable sterile males to be produced and released in requisite excess over the native population (Winston, 1997).

Other biological control methods include the release of insect pathogens (especially viruses, which are discussed in more detail below) (see Section 5.7.7.2 and **Chapters 6.8–6.10**), insect pheromones, and entomopathogenic fungi (reviews: Hall and Menn, 1999; Copping and Menn, 2000) (see **Chapter 6.11**).

5.7.7.2. Biological Control in the New Millennium

The genomics era has ushered in new methods of biological control. We now have the capacity to genetically manipulate insects and insect pathogens to have desired traits (Atkinson, 2002) (see **Chapter 5.12**). The potential benefits for insect release programs have been reviewed recently (Handler, 2002; Benedict and Robinson, 2003). The ability to engineer male sterility by genetic methods should increase success in future SIR programs by substantially improving the fitness level of released males. Moreover, genetic sexing techniques (Robinson, 2002) should enable facile elimination of females from the release population, which will enhance SIR by increasing the number of matings between sterile males and wild females.

An even more exciting development is the possibility of releasing insects carrying either a conditional lethal trait or female-killing allele (Handler, 2002). Both of these techniques, under optimal conditions, should be far superior to traditional SIR (Schliekelman and Gould, 2000a, 2000b). A conditional lethal trait that has been tested in *Drosophila*, but which has the advantage of being applicable to virtually all insect species that can be genetically manipulated, is temperature-sensitive alleles of genes encoding either diphtheria or ricin toxins. The insects are engineered to express only the A subunit of the toxin; in the absence of the B subunit that normally allows transmembrane movement, toxicity is cell-specific, thus preventing damage to predators. In principle, genes encoding insect-specific spider toxins could be used in a similar manner. It has been shown that the ω- and κ-atracotoxins can be expressed under heat shock control in *Drosophila*; insects are phenotypically normal at 18 °C but a heat shock to 37 °C

for just 10–15 min kills all flies (Tedford, Maggio, King, and Reenan, unpublished data). Since the toxins are not orally active, insects bearing these alleles would pose no threat to predatory organisms.

An alternative to SIR and parasite/predator release is incorporation of a transgene encoding a specific insecticidal component into the genome of plants or insect-specific pathogens. One recently introduced, and thus far highly successful, approach is the planting of transgenic crops that express insecticidal toxins, such as engineered corn and cotton crops that express δ-endotoxins from the soil bacterium *Bacillus thuringiensis* (Peferoen, 1997; Jenkins, 1999) (see **Chapter 6.6**). In addition to minimizing effects on nontarget organisms, *Bt* plants have generated increases in crop yields and significantly reduced insecticide use on many farms (Huang *et al*., 2002; Pray *et al*., 2002; Toenniessen *et al*., 2003). However, this technology has several potential drawbacks. First, constitutive expression of an insect toxin in transgenic plants is likely to expedite the development of resistance (Ferré and Van Rie, 2002; Morin *et al*., 2003), thus limiting the long-term benefit of the toxin transgene and compromising the effectiveness of *Bt* spores used widely by organic farmers. Second, some consumers are uncomfortable with, or philosophically opposed to, the introduction of nonplant proteins into their food (for a discussion of the emotive "Frankenfood" pejorative, see Dale (1999a, 1999b)). An additional concern associated with this technology is the possibility of transgene introgression into wild relatives of the engineered plant (Arnaud *et al*., 2003).

Bt endotoxins are uniquely suited to incorporation into transgenic plants as their activation is dependent upon the alkaline environment found in the gut of many insects, which ensures that these toxins are not active in humans and other vertebrates. In principle, the remarkable phyletic specificity of many spider-derived peptide neurotoxins makes them ideal for incorporation into transgenic plants. It was recently shown, for example, that rice transformed with a transgene encoding an insecticidal spider toxin was significantly less susceptible to infestation by the rice leaf-folder *Cnaphalocrocis medinalis* and striped stemborer *Chilo suppressalis* (Huang *et al*., 2001). However, most spider-derived polypeptide neurotoxins are not active when fed to insects, although it is possible that oral activity could be engineered by cofeeding with an agent that increases insect gut permeability, such as cytolytic peptides or even *Bt* endotoxins.

An alternative bioinsecticide strategy that is more specific, and which obviates the problem of introducing a foreign protein into the food supply, is the release of insect-specific viruses. Although there are many different types of insect viruses, all studies of this technology to date have focused on arthropod-specific baculoviruses, partly because of their proven inability to infect vertebrates (Gröner, 1986; Black *et al*., 1997; Kost and Condreay, 2002; Herniou *et al*., 2003). For most members of the nucleopolyhedrovirus (NPV) subgroup, infectivity is restricted to a few closely related lepidopterans, although some viruses only replicate efficiently in a single species (Black *et al*., 1997; Federici, 1999) (see **Chapter 6.8**). Thus, toxin exposure is limited to the targeted insect, while inculpable populations that are susceptible to chemical pesticides, including predators/parasites of the targeted insect, are unaffected.

Wild-type NPVs have become a key component of integrated pest management programs in several countries. They are used extensively in Brazil to protect soybean crops from the velvetbean caterpillar *Anticarsia gemmatalis* (Moscardi, 1999), and in China to safeguard cotton from the highly insecticide-resistant *Helicoverpa armigera* bollworm (Sun *et al*., 2002). In most situations, however, wild-type NPVs are not competitive with chemical pesticides because they typically take 5–10 days to kill their hosts, during which time the insect continues to feed and cause crop damage (Bonning and Hammock, 1996; Black *et al*., 1997). This shortcoming has been addressed by engineering recombinant baculoviruses that express heterologous insecticidal neurotoxins (Cory *et al*., 1994; Treacy, 1999; Inceoglu *et al*., 2001). Introduction of transgenes encoding peptidic neurotoxins from mites (Tomalski and Miller, 1991; Popham *et al*., 1997), scorpions (McCutchen *et al*., 1991; Stewart *et al*., 1991; Gershburg *et al*., 1998; Sun *et al*., 2002), spiders (Prikhod'ko *et al*., 1996, 1998; Hughes *et al*., 1997), and sea anemones (Prikhod'ko *et al*., 1996, 1998) have all been demonstrated to reduce the time interval between virus application and cessation of feeding or death (**Figure 2**). Importantly, introduction of a toxin transgene does not appear to alter the intrinsic infectivity of the virus or its natural host range (Black *et al*., 1997). (For more in depth discussion of naturally occurring and genetically modified baculoviruses see **Chapters 6.8** and **6.9**.)

Few attempts have been made to enhance the insecticidal efficacy of baculoviruses by incorporation of spider toxin transgenes. This is rather surprising since, as outlined in **Figure 2**, the most dramatic improvement obtained thus far in the insecticidal activity of *Autographa californica* NPV (AcNPV) resulted from incorporation of a transgene encoding μ-agatoxin IV from the American funnel-web spider

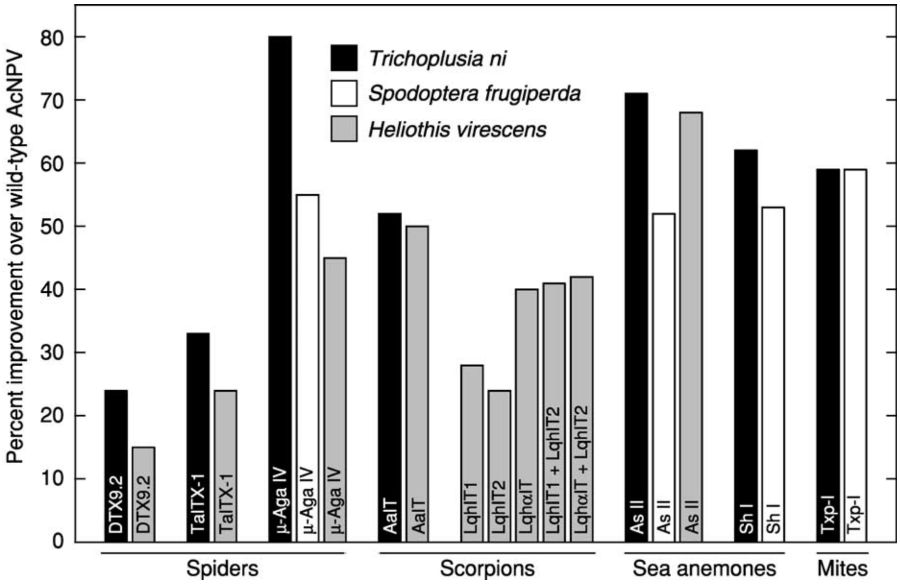

Figure 2 Histogram displaying the percent improvement (relative to wild-type virus) in the time required for 50% of a test population to be killed/paralyzed after feeding on *Autographa californica* nucleopolyhedrosis virus (AcNPV) engineered to contain transgenes encoding various arachnid or sea anemone toxins. It was difficult to make valid comparisons between studies because of differences in the manner of transgene insertion, choice of promoter driving the transgene, toxin signal sequence, and method of bioassay. Thus, this comparison is restricted to studies that used similar AcNPV constructs and which tested the virus on tobacco budworm (*Heliothis virescens*, light gray bars), fall armyworm (*Spodoptera frugiperd*a, white bars), or cabbage looper (*Trichoplusia ni*, black bars). In studies where a number of different constructs of the same transgene were tested, the construct that gave the best improvement over wild-type virus is reported here. Toxins are grouped taxonomically and their names are indicated on the histogram. (Data are from Lu, A., Seshagiri, S., Miller, L.K., **1996**. Control 12*, 79–87; Prikhod'ko, G.G., Popham, H.J.R., Felcetto, T.J., Ostlind, D.A., Warren, V.A., *et al.*, **1998**. Effects of simultaneous expression of two sodium channel toxin genes on the properties of baculoviruses as biopesticides. *Biol. Control 12*, 66–78; and Regev, A., Rivkin, H., Inceoglu, B., Gershburg, E., Hammock, B.D., *et al.*, **2003**. Further enhancement of baculovirus insecticidal efficacy with scorpion toxins that interact cooperatively. *FEBS Lett. 537*, 106–110.)

Agelenopsis aperta. However, a complicating factor in comparing outcomes from different studies (apart from different bioassay strategies, as discussed in Treacy (1999)) is that the efficiency with which a particular toxin is expressed and folded in virus-infected insects is generally not determined. A highly potent insecticidal neurotoxin could be ineffective as a baculoviral transgene because the toxin fails to be properly processed and/or folded in virus-infected insects. This is a critical issue because all of the arachnid and sea anemone toxins used to enhance baculoviral efficacy contain three to seven disulfide bonds, and the number of possible disulfide isomers increases dramatically as the number of cysteine residues increases; for example, six cysteines can be paired in 15 different ways to form three disulfide bonds, whereas eight cysteines can be covalently linked in 105 different ways to form four disulfide bridges. Thus, if a toxin with four disulfide bonds folded in a completely stochastic manner, the yield of correctly folded toxin would be <1%. In this respect, it is worth noting that heterologous expression systems have not been developed for any of the spider toxin genes previously used to generate recombinant baculoviruses, and hence it is unknown whether significant amounts of properly folded, bioactive spider toxin are produced in virus-infected insects.

The ω- and κ-atracotoxins appear to be excellent prospects for engineering viral bioinsecticides. They are the only insect-specific spider toxins for which heterologous expression systems have been developed (Tedford *et al.*, 2001; Maggio and King, 2002), they fold efficiently even in the absence of cellular folding enzymes (Wang *et al.*, 2000, 2001; Tedford *et al.*, 2001), and bioactive toxin is expressed when transgenes encoding these toxins are introduced into *D. melanogaster* (Tedford, Maggio, King, and Reenan, unpublished data). Our preliminary studies indicate that AcNPV expressing either ω-ACTX-Hv1a or κ-ACTX-Hv1c transgenes kills *Heliothis*

virescens more quickly than wild-type virus; moreover, potency can be significantly improved by expressing both toxins simultaneously in the pest insect (Maggio, Mukherjee, and King, unpublished data). Coexpression of synergistic toxin combinations (Herrmann *et al.*, 1995; Prikhod'ko *et al.*, 1998) appears to be a promising avenue for future investigations since it was also recently noted that baculoviral efficacy could be improved by synergistic expression of excitatory and depressant scorpion neurotoxins (Regev *et al.*, 2003).

Viruses that target disease vectors have also been isolated, including NPVs specific for the mosquito genera *Aedes*, *Anopheles*, and *Culex* (Becnel *et al.*, 2001; Moser *et al.*, 2001). Until recently, none of these NPVs had been characterized at the molecular level. However, the genome sequence was recently determined for an exotic baculovirus specific for *Culex* mosquitoes (CuniNPV), which are key vectors of St. Louis encephalitis, Eastern equine encephalitis, and West Nile virus in the United States (Afonso *et al.*, 2001). This work opens up the possibility of incorporating spider toxin transgenes into CuniNPV and related mosquito viruses in order to improve their efficacy.

5.7.8. Spider Toxins as Templates for Mimetic Design

In general, polypeptides are not good drugs because of their poor pharmacokinetic properties (Latham, 1999). Linear peptides are typically not even good drug leads because their interconversion between a plethora of different solution conformations makes it difficult to elucidate meaningful structure–activity relationships (Kieber-Emmons *et al.*, 1997). In contrast, conformationally constrained peptides and peptidomimetic libraries have emerged as valuable tools in the drug discovery process. The cystine knot toxins found in spider venoms are more akin to these libraries with one exception: the spider toxins come preoptimized for the desired target. Cystine knot toxins essentially comprise a robust structural scaffold (the cystine framework) onto which four loops are tethered, each bounded by half-cystines (Tedford *et al.*, 2001). As outlined above (see Section 5.7.5.2), spiders have been performing combinatorial chemistry with this framework on an evolutionary timescale, randomly changing residues in the intercystine loops and selecting those peptides that are most effective in helping to kill or paralyze their insect prey.

Thus, in principle, the long evolutionary history of ICK spider toxins should ensure that they are better leads than those resulting from screens of peptide or peptidomimetic libraries. Why then have they not been utilized for rational insecticide design? The answer is obvious from a quick glance at **Table 1**. For rational design, one needs to know not just the three-dimensional structure of the toxin, but also the spatial arrangement of residues that are critical for interaction with the toxin target. Although dozens of peptide toxins have been isolated from spider venoms over the past 15 years, the target binding site, or "insectophore," has only been elucidated for ω-ACTX-Hv1a (Tedford *et al.*, 2001, 2004) and κ-ACTX-Hv1c (Maggio and King, 2002), and these insectophores were only mapped in the past 2 years.

Elucidation of the target binding sites for ω-ACTX-Hv1a (**Figure 3a**) and κ-ACTX-Hv1c (**Figure 3b**) provides an opportunity for rational design of small molecule mimetics based on the mapped insectophores, a process refered to as "insectophore cloning." Several recent examples have provided encouraging validation of this concept (review: Norton *et al.*, 2003). Particularly relevant are three recent studies that involved cloning the pharmacophores of peptide toxins that block vertebrate calcium or potassium channels (Menzler *et al.*, 2000; Baell *et al.*, 2001, 2002). In each case, an attempt was made to rationally design nonpeptidic analogs that topologically mimicked the functional moieties corresponding to three key amino acid hits from mutagenesis studies. In the most successful study, an attempt was made to clone the pharmacophore of the cone snail ICK peptide ω-conotoxin MVIIA, a specific blocker of vertebrate N-type VGCCs and a lead for the development of novel analgesics. An alkylphenyl backbone was decorated with chemical groups corresponding to the key functional residues Arg10, Leu11, and Tyr13 (**Figure 3c**). Even though other ω-conotoxin MVIIA residues are involved in the toxin–channel interaction, the rationally designed mimics nevertheless had IC_{50} values of ~3 μM against human N-type VGCCs (Menzler *et al.*, 2000).

Thus, it should be possible to clone topologically restricted spider toxin insectophores to produce nonpeptidic lead compounds with low micromolar potency against the desired insect targets. What remains to be determined is whether a rationally designed mimic can maintain the desired phyletic specificity of the parent toxin. An obvious caveat is that residues deemed not to be functionally important according to mutagenesis studies might nevertheless provide a steric impediment to binding to the vertebrate counterpart of the targeted insect channel. Failure to take this into account might lead to phyletically indiscriminate mimics.

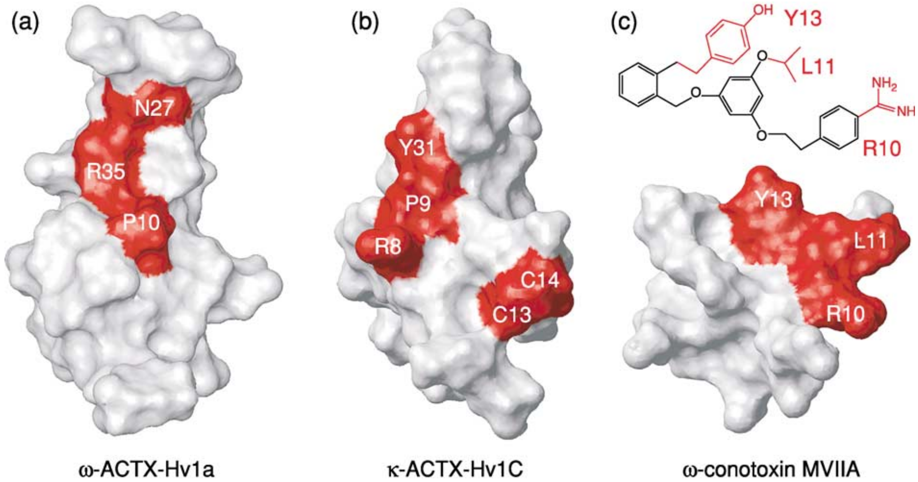

Figure 3 Molecular surface representation of (a) ω-ACTX-Hv1a (Protein Data Bank file 1AXH), (b) κ-ACTX-Hv1c (Protein Data Bank file 1DL0), and (c) ω-conotoxin MVIIA (Protein Data Bank file 1OMG) showing the channel binding surfaces (red) as mapped by mutagenesis studies (Nadasdi *et al.*, 1995; Tedford *et al.*, 2001, 2004; Maggio and King, 2002). Also shown in (c) is a rationally designed mimetic of the ω-conotoxin MVIIA pharmacophore, which blocks cloned human N-type VGCCs with $IC_{50} \sim 3\,\mu M$ (Menzler *et al.*, 2000).

5.7.9. Future Directions

Following a decade in which research on spider venoms was focused primarily on vertebrate-active compounds, there has been an acceleration of interest in recent years in the isolation and characterization of insect-specific toxins. So far, however, this immense reservoir of insecticidal compounds has been sparsely sampled, and it can be expected that many more insect-specific spider toxins will be isolated over the next few years. What remains to be seen is whether this basic research can be translated into viable insect control methods. In too few cases has there been a concerted effort to uncover the molecular target of these toxins, determine their three-dimensional structure, and elucidate detailed structure–function relationships. It is striking that the target binding site has been mapped in detail for only two spider toxins. Nevertheless, with appropriate focus on these aspects, it is likely that peptidic neurotoxins from spider venoms will facilitate discovery of new insecticide targets and provide molecular templates for rational design of novel chemical insecticides that act at these sites. Moreover, it should be possible to employ these spider toxins as bioinsecticides by incorporating genes encoding these toxins into insect-specific viruses, or by using such genes as conditional lethal alleles in transgenic insects.

Acknowledgments

We would like to acknowledge our many collaborators, especially Roger Drinkwater, Simon Gunning, Graham Nicholson, Robert Reenan, and David Wilson for allowing us to discuss unpublished collaborative results. Thanks to Susan Rowland and Scott Chouinard for critical appraisal of the manuscript, and to US National Science Foundation and the NIH National Institute of Allergy and Infectious Diseases for financial support.

5.8 Insecticidal Toxins from *Photorhabdus* and *Xenorhabdus*

R H ffrench-Constant, N Waterfield, and P Daborn, University of Bath, Bath, UK

5.8.1. Introduction

5.8.1.1. The Biology of *Photorhabdus* and *Xenorhabdus*

5.8.1.1.1. Bacteria, nematodes, and insects *Photorhabdus* and *Xenorhabdus* bacteria live in association with nematodes from the families Heterorhabditidae and Steinernematidae, respectively (Forst *et al*., 1997). Both genera bacteria are members of the Enterobacteriaceae, and are found as symbionts within the guts of the infective juvenile nematodes (ffrench-Constant *et al*., 2003). These infective juvenile nematodes seek out and invade insects, whereupon the bacteria are released from the mouth of the nematode directly into the insect blood system or hemocoel (Forst *et al*., 1997). The bacteria then multiply rapidly within the insect, apparently unaffected by the insect immune system (Silva *et al*., 2002). In the case of *Photorhabdus*, the bacteria first colonize the gut and grow rapidly in the hemocoel only, later colonizing all the other insect tissues (Silva *et al*., 2002). The nematodes also multiply within the insect cadaver, feeding off both the bacteria and the degraded insect tissues (Forst *et al*., 1997). Finally, a new generation of infective juvenile nematodes reacquires the bacteria and leaves the insect in search of new hosts.

During the course of this infection process the insect dies and the bacteria are inferred to secrete a range of toxins capable of killing the insect or attacking specific tissues (ffrench-Constant *et al*., 2003). For the purposes of this chapter, it is important to note that during this process the bacteria lie within the hemocoel of the insect or within the insect tissues. Therefore, any toxin action on the gut *in vivo* is likely to be from the hemocoel side of the gut. The existence of toxins acting from the lumen side of the gut is therefore, unexpected from the biology of the organism (Bowen *et al*., 1998). In this respect, this chapter is divided into sections on the orally active Toxin complexes (Tc's) and on the injectably active *M*akes *c*aterpillars *f*loppy (Mcf) toxins.

5.8.1.1.2. Bacterial nomenclature As this chapter involves the description of toxins from a wide range of *Photorhabdus* and *Xenorhabdus* strains, some description of current bacterial taxonomy is necessary to clarify subsequent discussion. The genus *Xenorhabdus* contains a number of species including *X. nematophilus*, *X. beddingii*, *X. bovienii*, and *X. poinarii* (Forst *et al*., 1997). The taxonomy of the genus *Photorhabdus*, however, is more complicated and has recently been revised. In this revision (Fischer-Le Saux *et al*., 1999), the genus was recently split into three species, *P. luminescens*, *P. temperata*, and *P. asymbiotica*. Two of these genera have also been subdivided into new subspecies. Thus, the *P. luminescens* group has three subspecies, *luminescens, akhurstii*, and *laumondii*, and the *P. temperata* group has one subspecies, *temperata*. The third species group, *P. asymbiotica*, which consists of isolates from human wounds recovered in the apparent absence of a nematode vector (Gerrard *et al*., 2003), has not yet been subdivided. Most of the genetic analyses have been performed on a limited number of strains: *P. luminescens* subsp. *akhurstii* strain

W14, *P. luminescens* subsp. *laumondii* strain TT01, and *P. temperata* strains K122 and NC1. For brevity these strains will be referred to as *Photorhabdus* strains W14, TT01, K122, or NC1, or simply W14, TT01, K122, and NC1, except where reference to their different specific designation is relevant to the discussion.

5.8.1.2. The Need for Alternatives to Bt

To date, the majority of transgenes deployed in insect resistant crops are *Cry* genes from *Bacillus thuringiensis* or "Bt." Despite the diversity of *Cry* genes cloned from *B. thuringiensis*, only a few Cry proteins are toxic towards specific pests. This observation has led to concerns about the development of resistance to specific Cry toxins and over the subsequent management of cross-resistance to other toxins occupying the same or similar binding sites (Ives, 1996; McGaughey *et al.*, 1998). These concerns are increasing as specific cases of laboratory-developed Bt resistance are documented in pest insects (McGaughey, 1985; Gahan *et al.*, 2001). *Bacillus thuringiensis* has also proved to be a useful source of other non-*Cry* genes such as the vegetative insecticidal proteins or "Vips" (Estruch *et al.*, 1996; Yu *et al.*, 1997); however, this organism clearly has a limited capacity to produce further toxins. The work described here on the isolation and characterization of insecticidal toxins from *Photorhabdus* and *Xenorhabdus* has been performed partly in the search for alternative novel insecticidal proteins for insect control.

5.8.2. The Toxin Complexes

5.8.2.1. Discovery of the Toxin Complexes

5.8.2.1.1. Purification and cloning of *Photorhabdus* toxins Despite the fact that *Photorhabdus* is released directly into the insect hemocoel by its nematode host, the culture supernatant of *Photorhabdus* strain W14 shows unexpected oral toxicity to the lepidopteran model *Manduca sexta* (Bowen and Ensign, 1998). A toxic high molecular weight-protein fraction was purified from the W14 supernatant by sequential ultrafiltration, dimethyl aminoethyl (DEAE) anion-exchange chromatography, and gel filtration (Bowen and Ensign, 1998). As a final purification step, high-performance liquid chromatography (HPLC) anion-exchange chromatography was used to separate four peaks or "Toxin complexes" A, B, C, and D (Bowen *et al.*, 1998). Purified Toxin complex A (Tca) has a median lethal dose of 875 ng cm^{-2} of diet against *M. sexta*, and is therefore as active as some Bt Cry proteins (Bowen *et al.*, 1998). The histopathology of orally ingested Tca shows the primary site of action to be the midgut, where cells of the midgut epithelium produce blebs as the epithelium itself disintegrates (Blackburn *et al.*, 1998). Interestingly, injection of purified Tca also results in destruction of the midgut with a similar histopathology, suggesting that Tca can act on the gut from either the lumen or the hemocoel (Blackburn *et al.*, 1998).

Each of the HPLC purified complexes migrates as a single or double species on a native gel but resolves into numerous different polypeptides on a denaturing sodium dodecylsulfate (SDS) gel (Bowen *et al.*, 1998). The *toxin complex* (*tc*) encoding genes were cloned by raising both monoclonal and polyclonal antisera against the purified complexes and using these to screen an expression library. Each of the four complexes Tca, Tcb, Tcc, and Tcd is encoded by four independent loci *tca, tcb, tcc*, and *tcd* (Bowen *et al.*, 1998). Each of these loci consists of an operon with successive open reading frames, for example, *tcaA, tcaB, tcaC*, and *tcaZ* (**Figure 1**). These open reading frames encode the different polypeptides that can be resolved from the native complexes as confirmed by N-terminal sequencing of the individual polypeptides resolved on an SDS gel (Bowen *et al.*, 1998). Genetic knockout of each of the *tca*, *tcb*, *tcc*, and *tcd* loci in turn showed that both *tca* and *tcd* contribute to oral toxicity to *M. sexta* and that removal of both these loci in the same strain renders the double mutant nontoxic (Bowen *et al.*, 1998).

Similar independent purification approaches to the supernatant of strain W14 identified two high molecular weight complexes, confusingly termed "toxin A" and "toxin B," with oral activity to the coleopteran *Diabrotica undecimpunctata howardi* (Guo *et al.*, 1999). These two toxins correspond to the species TcdA and TcbA, respectively, therefore confirming that both Tcd and Tcb also have activity against Coleoptera. The native molecular weights of TcdA and TcbA were estimated at 860 kDa, leading to the suggestion that they are tetramers of the 208 kDa species observed on an SDS gel (Guo *et al.*, 1999). These species can also be proteolytically cleaved by proteases found in the culture supernatant and an increase in insecticidal activity associated with the cleaved form of the toxin was reported (Guo *et al.*, 1999). However, the nature of the protease responsible and the relevance of the cleavage in the biological activity of the toxins remain obscure.

5.8.2.1.2. Cloning of *Xenorhabdus* toxins Supernatants of some *Xenorhabdus* strains also show oral

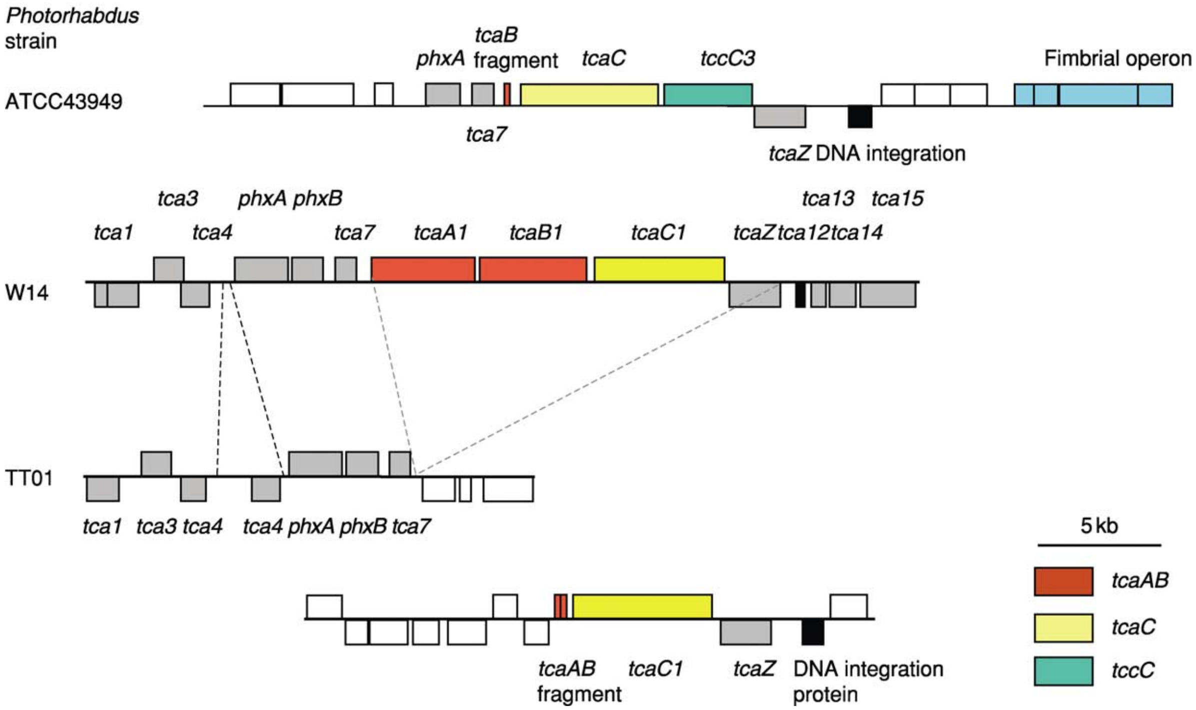

Figure 1 The *toxin complex a* (*tca*) locus from three different *Photorhabdus* strains highlighting the three different color-coded elements *tcaAB*, *tcaC*, and *tccC* (see key). Note that this locus is only complete in strain W14 (in which it confers oral toxicity) and that in TT01 the locus is deleted from the equivalent location in the genome and found as a partially complete copy elsewhere (see text for discussion).

toxicity to insects. Oral insecticidal activity against another lepidopteran, *Pieris brassicae*, was used to identify *tc* gene homologs from *X. nematophilus* PMF1296 (Morgan *et al*., 2001). In this study, a cosmid library was made in *Escherichia coli* and individual cosmids were screened for oral activity. Two overlapping cosmids with oral activity were recovered and one of these was completely sequenced. Transposon mutagenesis of the cosmids was then carried out to discover which open reading frames were involved in oral toxicity (Morgan *et al*., 2001). The genes encoding insecticidal activity were termed *Xenorhabdus protein toxins* (*xpt*) and insertions within the large gene *xptA1* were associated with a loss of oral activity (Morgan *et al*., 2001). The predicted amino acid sequences of the *xpt* genes show high similarity to the *tc* genes of *Photorhabdus* and their closest homologs have been indicated in a revised map of the open reading frames found in the cosmid (Figure 2). The orally toxic *Xenorhabdus* cosmid therefore contains two *tcdA* homologs transcribed in opposite directions (*xptA1* and *xpta2*) with *tcaC* (*xptC1*) and *tccC* (*xptB1*) homologs between them. Expression of one *tcdA*-like gene (*xptA1*) alone in *E. coli* was sufficient to reproduce oral activity in *E. coli* (Morgan *et al*., 2001). This data suggests that the two different genera of nematode symbionts use similar *toxin complex*-like genes.

5.8.2.1.3. Genomic organization of *Photorhabdus tc* genes Extended sequencing of the *tcd* locus in strain W14 revealed that clusters of *tcdA*-like genes were present in the *Photorhabdus* W14 genome (**Figure 3**). Further, these multiple *tcdA* and *tcdB*-like genes are inserted next to an AspV tRNA in a potential pathogenicity island (Waterfield *et al*., 2002). This island is a region of DNA inserted in putative "core" sequence, i.e., sequence similar to core sequences in *E. coli* and *Yersinia pestis*. The island contains multiple copies of *tccC*-like sequences, which may promote recombination, and also enteric repetitive intergenic consensus (ERIC) sequences (Waterfield *et al*., 2002). The region also contains numerous directly duplicated open reading frames and a fragment of a *tcdA*-like gene, suggesting that it may be prone to rearrangement. Finally, a comparison of pathogenicity islands or phage inserted at the Asp tRNA in other related bacteria shows similar genomic islands carrying other toxin genes and *rhs* elements in place of *tccC*-like elements (**Figure 4**). All these factors combine to support the concept that the *tcd*-island is a pathogenicity island. Moreover it is interesting to note that this island is adjacent to a

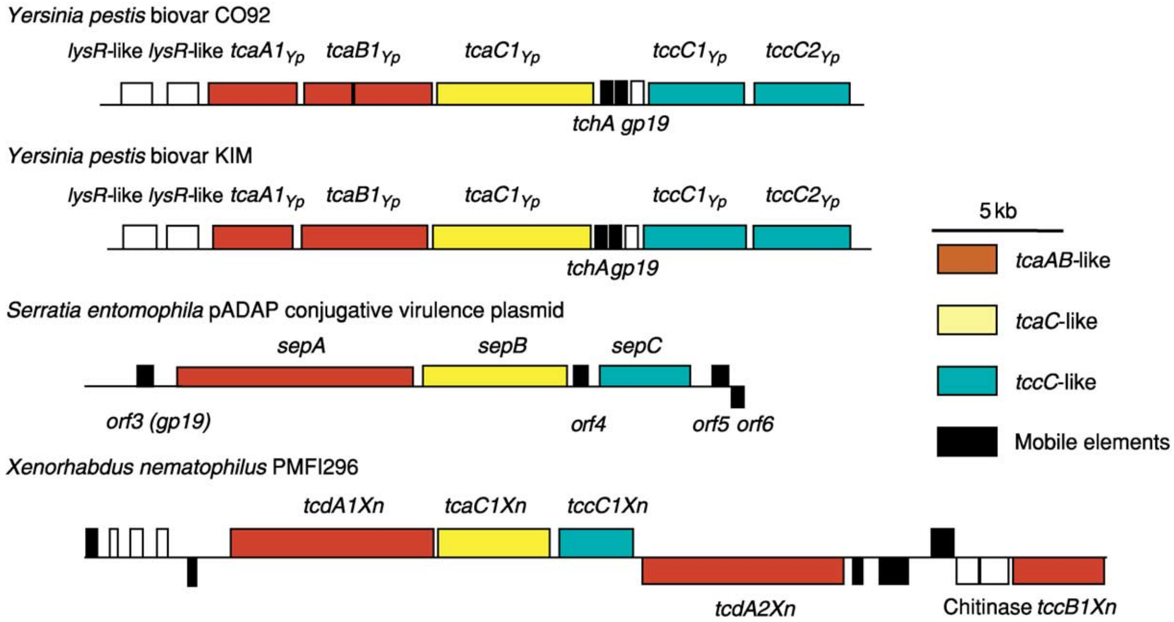

Figure 2 Comparison of *tc*-like loci in entomopathogenic bacteria. *Yersinia pestis* is vectored by the flea and carries a *tca*-like locus, complete in biovar KIM but with *tcaB1* disrupted in biovar CO92. *Serratia entomophila* is a free-living bacteria that infects grass grubs. In this species the *tc*-homologous *sepABC* is carried on a conjugative plasmid required for insect pathogenicity. In *Xenorhabdus nematophilus*, vectored by a nematode, *tc*-homologous genes lie on a cosmid clone recovered on the basis of oral toxicity to caterpillars. Note again that the color coding indicates homology with the three central *tcaAB*, *tcaC*, and *tccC*-like elements (see key).

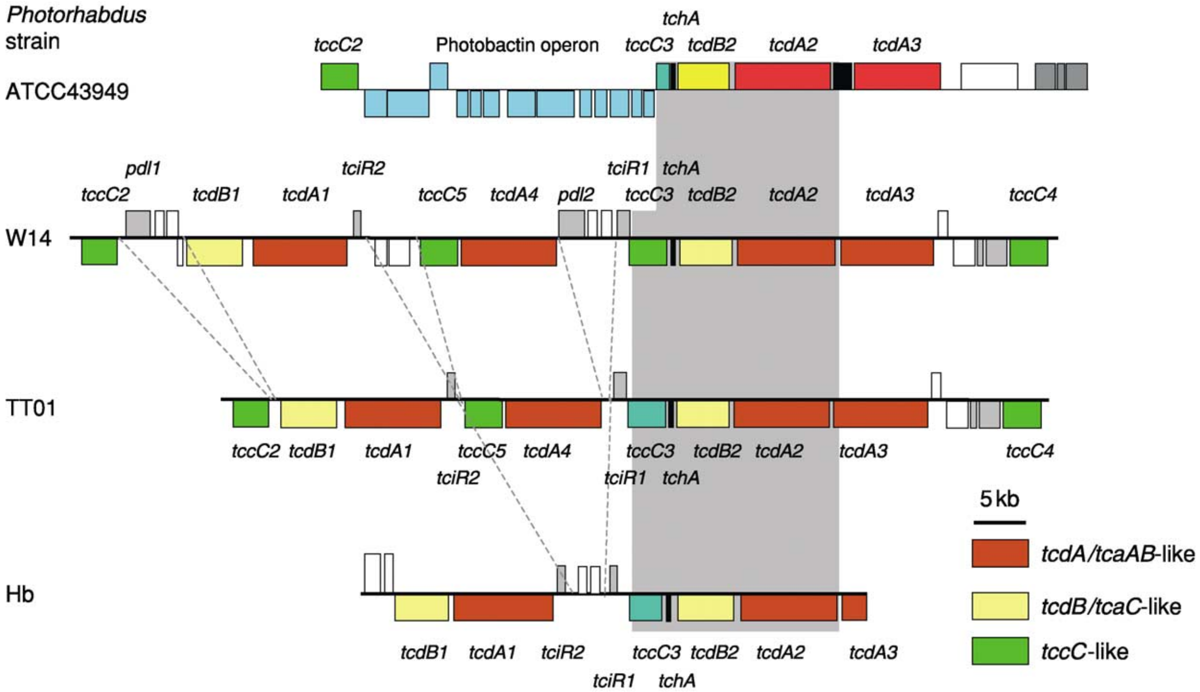

Figure 3 The *toxin complex d* (*tcd*) locus from four different *Photorhabdus* strains highlighting the three different color-coded *tcaAB/tcdA*, *tcaC/tcdB*, and *tccC*-like elements (see key). Comparison of the four loci shows a conserved core (boxed in gray) and then localized deletions within and between the different *tcd* homologs (see text). Note that the *tcd* locus from W14 can confer oral toxicity on recombinant *E. coli*.

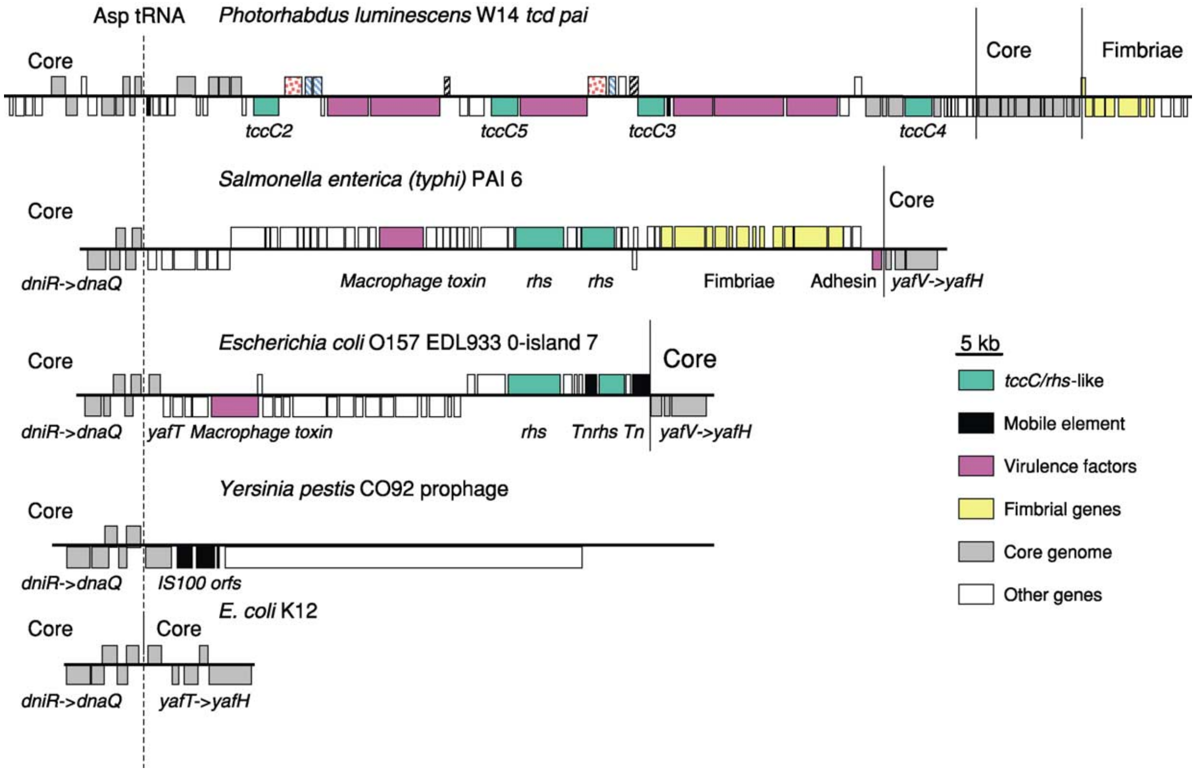

Figure 4 Comparison of *Photorhabdus* W14 *tcd* pathogenicity island with pathogenicity islands also inserted at the Asp tRNA in other related bacteria. The ''core'' sequence flanking the inserted island is shown. Note the common elements of the pathogenicity islands sharing insertion near a tRNA, toxin genes and mobile elements (see key).

gene *ngrA* implicated in nematode symbiosis (Ciche *et al*., 2001). Thus regions containing insect pathogenicity genes and nematode symbiosis factors may be linked in the W14 genome.

5.8.2.2. Homologs in Other Bacteria

Homologs of *tc* genes have now been found in other bacteria, both those pathogenic to insects and also bacteria with no obvious insect association (Waterfield *et al*., 2001b). Gene homologs are found in *Serratia entomophila*, a free-living bacterium causing "amber disease" in the New Zealand grass grub, *Costelytra zealandica* (Hurst *et al*., 2000). Larval disease symptoms after oral ingestion of *S. entomophila* include cessation of feeding, clearance of the gut, amber coloration, and eventual death. In *S. entomophila*, the disease determinants are encoded on a 115 kb plasmid designated pADAP, for amber disease-associated plasmid (Glare *et al*., 1993). Introduction of pADAP into *E. coli* is sufficient to confer oral toxicity on the whole bacteria (Hurst *et al*., 2000). The genes encoding the amber disease toxins were mapped to a 23 kb fragment of pADAP and then identified by insertional mutagenesis. The three disease-associated genes were termed *Serratia entomophila pathogenicity* (*sep*) genes (Hurst *et al*., 2000). These predicted products of these genes show high similarity to those of the *tc* genes and are again clearly homologs. Thus *sepA* is *tcd*-like, *sepB* is *tcaC*-like, and *sepC* is a *tccC*-like gene (**Figure 2**). The finding of *tc*-like genes in a bacterium with no known association with a nematode shows that this class of genes is not specific to nematode symbionts. Further, the presence of the *sep* genes on a plasmid supports the concept, derived from the *tcd* island of *Photorhabdus* W14 (Waterfield *et al*., 2002; ffrench-Constant *et al*., 2003), that the *tc* genes can be found on unstable or mobile stretches of DNA.

More recently, *tca*-like genes have also been discovered in both the sequenced genomes of *Y. pestis* (Parkhill *et al*., 2001; Deng *et al*., 2002), the causative agent of bubonic plague (Perry and Fetherston, 1997). Although highly pathogenic to man, *Y. pestis* is vectored by fleas and is therefore insect associated for part of its life cycle. Following uptake of an infected blood meal the midgut of the flea becomes "blocked," a process facilitating transmission of the infected blood to the next mammalian host (Hinnebusch *et al*., 1996). The hypothesis that the *tca* homolog in *Y. pestis* may be involved in midgut blockage was investigated by making a knockout

mutant of the gene and examining its effect on blood feeding in the flea. However, no direct effect of the *tca* mutant on midgut blockage was seen (ffrench-Constant, Perry, and Hinnebusch, unpublished data). The functional role of this gene in *Y. pestis* therefore remains unknown. The observation that one of the *tca* open reading frames is apparently disrupted in strain CO92 led Parkhill *et al.* (2001) to suggest the alternative hypothesis, that loss of *tca* function may actually be required for persistence of *Y. pestis* in the flea gut. Further, the presence of an intact *tca* homolog in the recent putative ancestor of *Y. pestis*, *Y. pseudotuberculosis* (S. Hinchcliffe, personal communication), supports the concept that *tca* function may have recently been lost.

Gene homologs can also be detected in the genomes of bacteria with no currently known associations with insects. In *Pseudomona syringae* pv tomato, there is a locus with *tcaC*, *tccB*, and *tccC* homologs (Figure 5). Although this bacterium has no known association with insects, as a plant pathogen it may have an undescribed insect vector. Finally, and most recently, *tc* homologs have been found in the genome of *Fibrobacter succinogenes*, a commensal of ruminants with no obvious insect association. This growing range of noninsect associated bacteria with *tc* gene homologs may suggest that this class of genes is widely found in Gram-negative bacteria and that insect toxicity has been acquired in only a limited subset of *tc* gene homologs. The inferred ancestral function of *tc* homologs, however, remains obscure.

5.8.2.3. Molecular Biology of the *toxin complex* Genes

5.8.2.3.1. *toxin complex* gene organization The previous survey of *tc* gene homologs found in a range of bacteria leaves us with a confusing array of gene names and homologies. However, several aspects of the genomic organization of these genes in different species begin to indicate which may be the minimal functional units of insect toxicity. First, a color-coded comparison of *tc* loci in different bacteria shows that the different loci are mainly variations on a simple theme of three basic gene types: (1) *tcdA*-like genes, (2) *tcaC*-like genes, and (3) *tccC*-like genes (Figures 1–3). Second, where isolated pieces of DNA can confer oral toxicity, such as the pADAP plasmid of *S. entomophila* (Hurst *et al.*, 2000) and the cosmids isolated from *X. nematophilus* (Morgan *et al.*, 2001), only these same three gene types are required for full toxicity. This effectively gives us a working hypothesis for attempts to recombinantly express *Photorhabdus* toxins, i.e., that combinations of these three types of genes are required for the expression of full oral toxicity.

5.8.2.3.2. Expression and structure of *Photorhabdus* toxins Following the demonstration that knockout of either *tca* or *tcd* in *Photorhabdus* W14 decreases oral toxicity and in the absence of orally toxic cosmids carrying these loci, it was required to define the minimal components necessary for full oral toxicity in *E. coli*. In these experiments plasmids were inserted into *E. coli* carrying either (1) *tcdA* alone, (2) *tcdA* and *tcdB*, or (3) *tcdA*, *tcdB*, and *tccC* together. Only the plasmid carrying all three genes confers oral toxicity when expressed in *E. coli* and toxicity is increased by induction of the culture with mitomycin, suggesting that Tc production may be related to stress induced by this phage-inducing agent. Electron microscopy of high molecular weight particle preparations of the recombinant protein showed the Tc complexes to be "ball

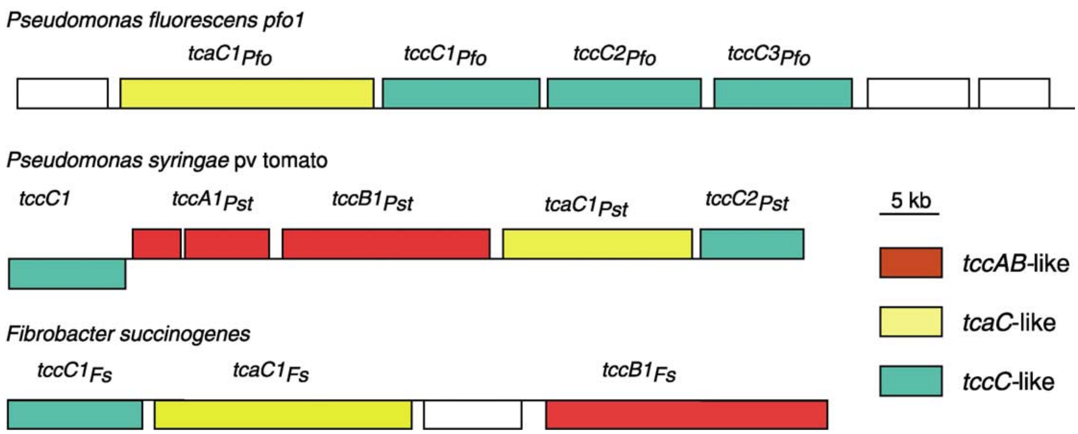

Figure 5 Comparison of *tc*-like loci in bacteria with no known insect association showing that *tc*-like genes can also be found in plant pathogens with no known insect vector like *Pseudomonas syringae* and even ruminal commensals like *Fibrobacter succinogenes* (see text for discussion).

and stick" shaped particles of 25 nm in length (Waterfield *et al.*, 2001a). Further, despite the fact that the presence of *tccC* is necessary for full oral toxicity, the particles themselves can be made by *tcdA* and *tcdB* alone. This suggests that TccC plays a critical role in the activation or export of the complex but does not change the physical structure of the *tcdAB*-derived structure.

Finally, despite the unexpected oral activity of the Tc toxins, how does *Photorhabdus* itself employ these toxins in a normal infection? Immunocytochemistry using an anti-TcaC antibody in insects infected with *Photorhabdus* W14 shows that Tca is produced during infection of the insect midgut (Silva *et al.*, 2002). During infection, the bacteria occupy specific grooves in the midgut, penetrating under the sheathing extracellular matrix to lie directly underneath the midgut epithelium. Within this sheltered niche the bacteria produce Tca, much of which appears to be associated with the bacterial outer membrane (Silva *et al.*, 2002). In this fashion the gut active toxin can be delivered in extreme proximity to the midgut epithelium itself.

5.8.3. The Makes Caterpillars Floppy Toxins

5.8.3.1. Discovery of Makes Caterpillars Floppy

5.8.3.1.1. Cloning of *mcf1* Although the Tc's account for the oral toxicity of some *Photorhabdus* supernatants, the nature of the toxins used by the bacteria growing within the hemocoel to actually kill the insect host remain unclear. To investigate potentially injectably active toxins individual cosmids were employed but this time injecting *E. coli* cultures carrying each cosmid individually into *M. sexta* caterpillars (Daborn *et al.*, 2002). By injecting 2×10^7 cells per culture, 300 clones were injected and a single cosmid that resulted in death of the insect was recovered. As well as killing the insect, the cosmid also induced a rapid loss of body turgor, termed the "floppy" phenotype (Daborn *et al.*, 2002). The cosmid was mutagenized with 126 single transposons to look for insertions showing the loss of either phenotype. The same insertions were also used as entry points to sequence the complete cosmid and identify open reading frames. Out of 126 insertions, 39 negated both phenotypes and all of these lay within a single 8.8 kb gene. This gene also caused both death and loss of body turgor when *E. coli* carrying this gene alone were injected into carterpillars. Therefore, this open reading frame was termed the *makes caterpillars floppy* gene or *mcf*. This open reading frame predicts a high molecular weight protein of 324 kDa. However, the predicted protein shows little homology to other proteins in the databases. Three regions of limited homology are present (**Figure 6**). First, the C-terminus shows similarity to a repeated sequence found in RTX-like toxins (Schaller *et al.*, 1999) potentially involved in toxin secretion. Second, part of the central domain is similar to the translocation domain from toxin B of *Clostridium difficile* (Hofmann *et al.*, 1997). Finally, a region in the N-terminus matches the consensus sequence for a Bcl-2 homology domain 3 (BH3) domain. Vertebrate proteins involved in apoptosis that contain only this domain

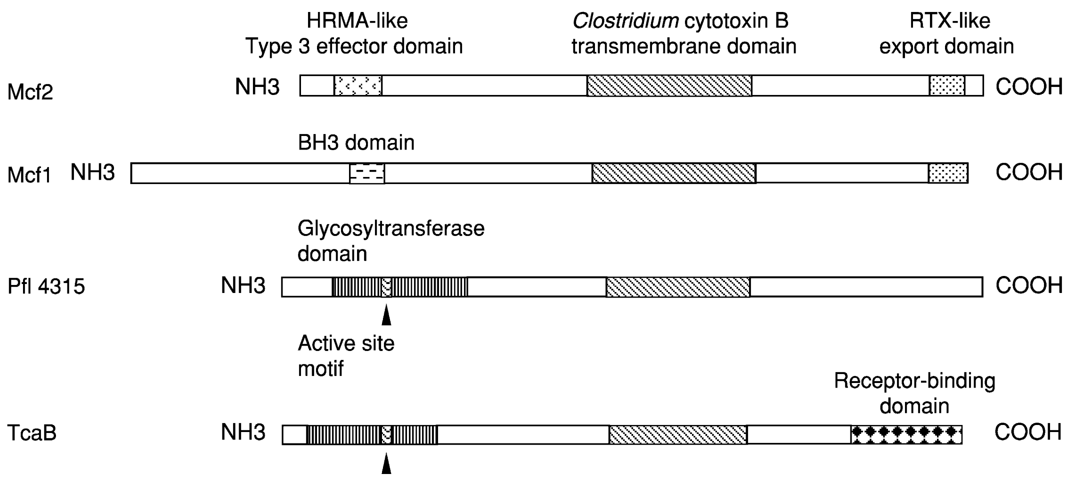

Figure 6 The Makes caterpillars floppy (Mcf) toxins 1 and 2 compared to toxins from *Pseudomonas fluorescens* (Pfl 4315) and *Clostridium* (confusingly termed TcaB but not a Tc toxin). Both Mcf1 and Mcf2 have domains in their N-termini putatively associated with apoptosis, namely a BH3 and HRMA-like domain, respectively. Two regions of similarity within this class of toxins are highlighted. First a transmembrane domain found in the *Clostridium* toxin and second an RTX-like export domain found in the C-terminus of both Mcf proteins.

are proapoptotic (Budd, 2001), leading to the working hypothesis that Mcf itself may also promote apoptosis. Interestingly, if proved, this would be the first BH3 domain found outside of eukaryotes.

The observation that *E. coli* expressing Mcf alone can survive in the presence of the insect immune system is unexpected. Normally, *E. coli* carrying a pUC18 plasmid are cleared from the insect, presumably via the action of both antibacterial peptides and the insect phagocytes or hemocytes. In contrast, *E. coli* carrying pUC18-*mcf* and a second green fluorescent protein (GFP) expressing plasmid persist longer in the hemolymph. Dissection of infected animals shows that the Mcf and GFP expressing bacteria can colonize tissues in the insect and that the hemocytes fail to encapsulate the bacteria in melanin. Therefore, it was speculated that this failure to encapsulate Mcf expressing bacteria was due to hemocytes, dying via Mcf induced apoptosis. To investigate whether Mcf can promote apoptosis in hemocytes, the hemocyte monolayers were exposed to recombinant Mcf. The results show that exposed hemocytes, disintegrate rapidly, within 6 h, by producing numerous characteristic blebs. The residual actin cytoskeleton also shows a characteristic punctate pattern of staining. This proapoptotic effect on hemocytes helps to explain how recombinant *E. coli* can persist in the insect but fails to explain how the insects lose body turgor and die.

To examine the cause of the floppy phenotype, the histopathology of insects infected with *E. coli* expressing Mcf was investigated. Given that both the Malpighian tubules and the midgut are responsible for osmoregulation, destruction of either of these organs could result in a rapid loss of body turgor. Sections of infected caterpillars showed that the Malpighian tubules were intact at the time of death but cells of the midgut epithelium were severely affected as early as 12 h post injection. Both goblet and columnar cells shed circular blebs, often including the nucleus, into the midgut lumen. Nuclei within the dying cells appear pycnotic and stain terminal deoxynucleotidyl transferase-mediated duTP end labeling (TUNEL) positive, suggesting that they are apoptotic. These observations are consistent with Mcf having a proapoptotic function and with its primary site of action being the insect midgut. However, some caution is necessary in interpreting these results as insects ingesting *B. thuringiensis* Cry of Vip toxins also show a similar histopathology of the midgut. More specific experiments to show that Mcf is proapoptotic are therefore needed.

Comparison of the genomic location of *mcf1*-like genes between *Photorhabdus* strains confirms two important points (Figure 7). First, *mcf1*-like genes appear to be present in all strains of *Photorhabdus*, as would be expected if Mcf1 is a dominant toxin. Second, like the *tc* toxins, the location of *mcf1* differs between genomes and is often associated with either a Phe tRNA or integrase genes. In fact in strain TT01, *mcf1* is adjacent to a Phe tRNA on one side and the downstream of the *tccC* locus, suggesting that in this case both a *tc* and *mcf* locus may be found together on the same pathogenicity

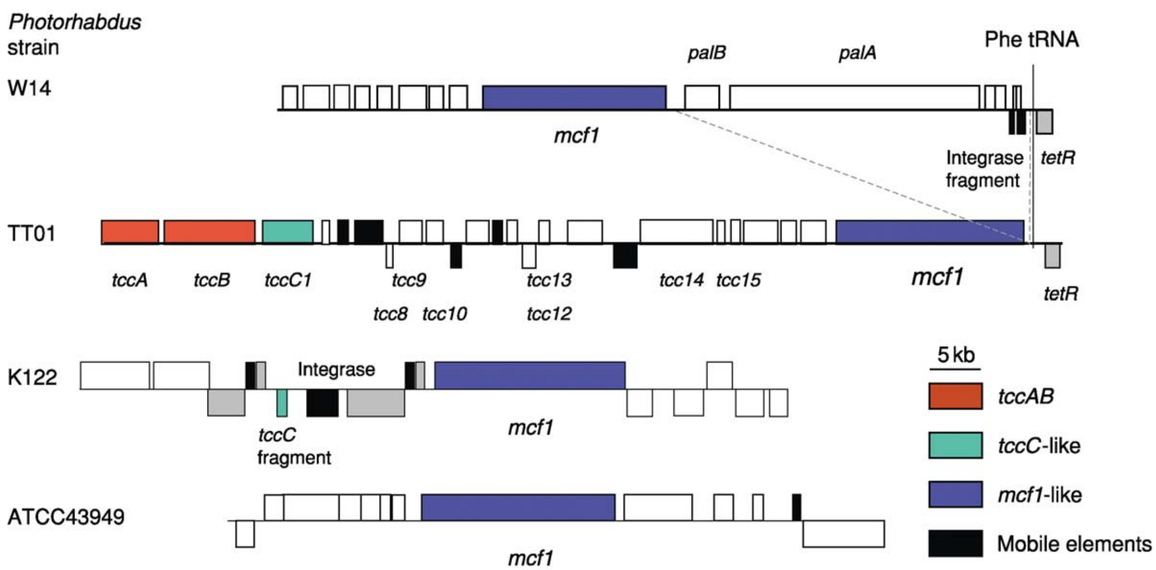

Figure 7 Comparison of *mcf1* containing loci from four different *Photorhabdus* strains. Note that *mcf1* lies alongside a Phe tRNA in both W14 and TT01; however, W14 also carries *palBA*. In the other two strains sequenced, K122 and ATCC43949, *mcf1* appears to occupy different genomic locations suggesting that the toxin is mobile within the *Photorhabdus* genome.

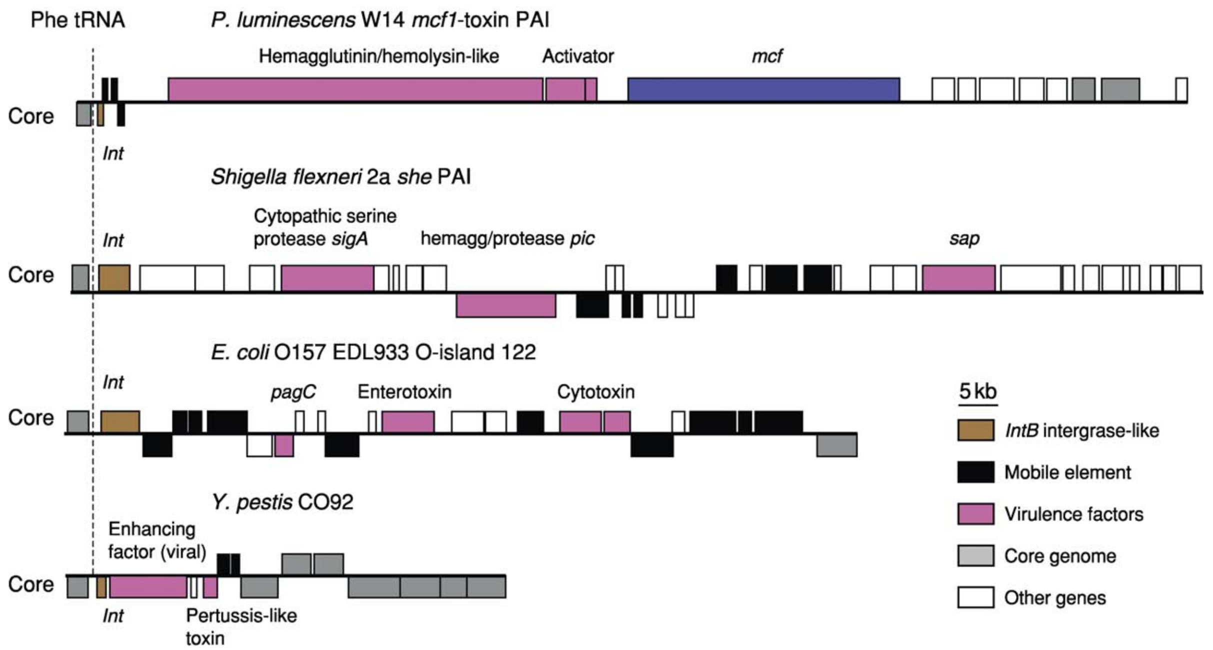

Figure 8 Comparison of *Photorhabdus* W14 *mcf1* pathogenicity island with pathogenicity islands also inserted at the Phe tRNA in related bacteria. The ''core'' sequence flanking the inserted island is shown. Note the common elements of the pathogenicity islands sharing insertion near a tRNA, toxin genes and mobile elements (see key). Note also the similarities in genomic organization with the *tcd* island in Figure 4.

island. Finally, comparison of the relative genomic location of the island containing *mcf1* in *Photorhabdus* strain W14 with other islands inserted at the Phe tRNA in related bacteria again show a similar pattern with other toxins being inserted alongside integrase genes or integrase gene fragments (Figure 8). This confirms that *Photorhabdus*, like related enteric bacteria, carries a range of toxin encoding pathogenicity islands inserted at tRNA genes.

5.8.3.1.2. Cloning of *mcf2* homologs Sample sequencing of the *P. luminescens* W14 genome revealed the presence of a second *mcf*-like open reading frame termed *mcf2*. The predicted Mcf2 protein is similar to Mcf1 (Figure 6) but is significantly shorter at the N-terminus. Further, rather than carrying BH3-like domain, part of the N-terminus shows similarity to HrmA from *Pseudomonas syringae* pv. *syringae* (Figure 6). The *hrmA* gene encodes a protein that has an avirulence (*avr*) phenotype in plants, travels a type III (Hrp) secretion system, and also elicits cell death when transiently expressed directly in tobacco cells. This suggests that HrmA is a type III delivered effector that can cause apoptosis in plant cells. The similarity of HrmA with part of Mcf2 suggests that Mcf2 may also be involved in inducing apoptosis but via a different mechanism than Mcf1. In this case, it is interesting to note how a type III effector protein such as HrmA, which is normally delivered directly into the cell, has become fused within the N-terminus of Mcf2 to be delivered within the high molecular weight protein via an undescribed mechanism. Comparisons of available sequence data from different *Photorhabdus* strains suggests that copies of *mcf1* are always present, suggesting it may be the dominant insect killing toxin (Figure 7). However, we remain uncertain about the distribution of *mcf2* and although this toxin is present in W14 and TT01, this gene is not present in currently available sequence from the *P. asymbiotica* isolate being sequenced at the Sanger Center. It is therefore not clear if *mcf2* is a required toxin present in all *Photorhabdus* strains like *mcf1* or if it is only present in a subset of strains.

5.8.4. Toxin Genomics

5.8.4.1. Microarray Analysis

The widespread distribution of the *tc* genes between different bacteria raises interesting questions as to their origins and transmission. To examine these questions in *Photorhabdus* strains the simple question should be answered: is oral toxicity monophyletic? In other words, do all *Photorhabdus* strains with orally toxic supernatants belong to the same

taxonomic group? To address this question, two parallel approaches were used. First, phylogenetic analysis of orally toxic and nonorally toxic strains using 16S DNA sequences was carried out. Second, hybridized genomic DNA from each strain to a microarray carrying 96 putative virulence factor genes from the orally toxic *Photorhabdus* strain W14 was done to investigate the minimal subset of *tc* genes required for oral toxicity.

The phylogenetic analysis showed that the six orally toxic strains examined fell into two distinct taxonomic groups. The first (IS5, EG2, IND, and W14 itself) lies within the previously recognized *P. luminescens* subsp. *akhurstii* subspecies. The second (Hb1 and Hm1) represents a different subgroup, *P. luminescens* subsp. *luminescens* (Figure 9). The microarray analysis also revealed groups of genes either conserved or variable between the strains examined (Figure 10). Conserved genes included genes such as *lux*, which produces light, a phenotype common to all *Photorhabdus* (Forst and Nealson, 1996). A series of putative virulence factors also appear conserved in most, or all, strains, including the toxin encoding gene *mcf1* (Daborn *et al.*, 2002), *rtxA1* and *rtxA2*-like genes, the operon encoding the *prtA* protease, and an *attachment and invasion locus* (*ail*) homolog (ffrench-Constant *et al.*, 2003). The type III secretion system (Waterfield *et al.*, 2002), often associated with virulence in other Gram-negative bacteria (Galan and Collmer, 1999), is also present in all strains. Other conserved genes include those encoding catalase, chitinase, ferrochetalese, and flagellae. Variable genes include bacteriocins, toxins/hemolysins, insertion elements, pili,

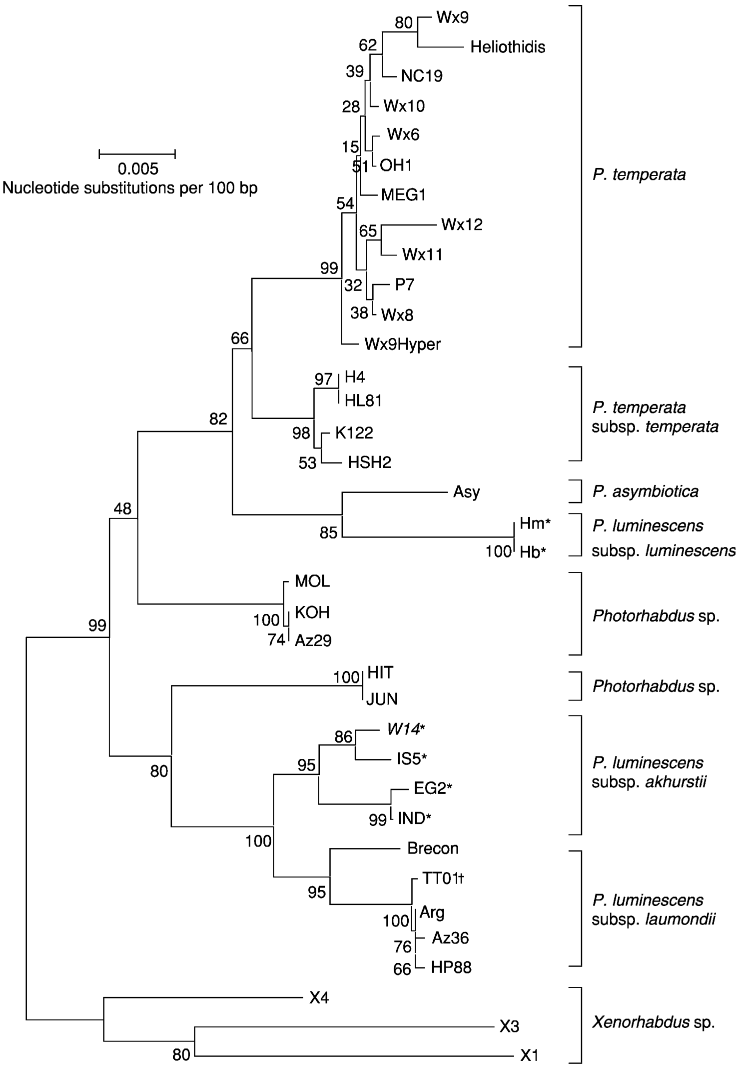

Figure 9 Phylogenetic analysis of orally and nonorally toxic strains used in the microarray analysis based on 16s DNA sequencing. Note that orally toxic strains (*) fall into two well-supported phylogenetic groups. Strain TT01 (†) has recently been completely sequenced (see text).

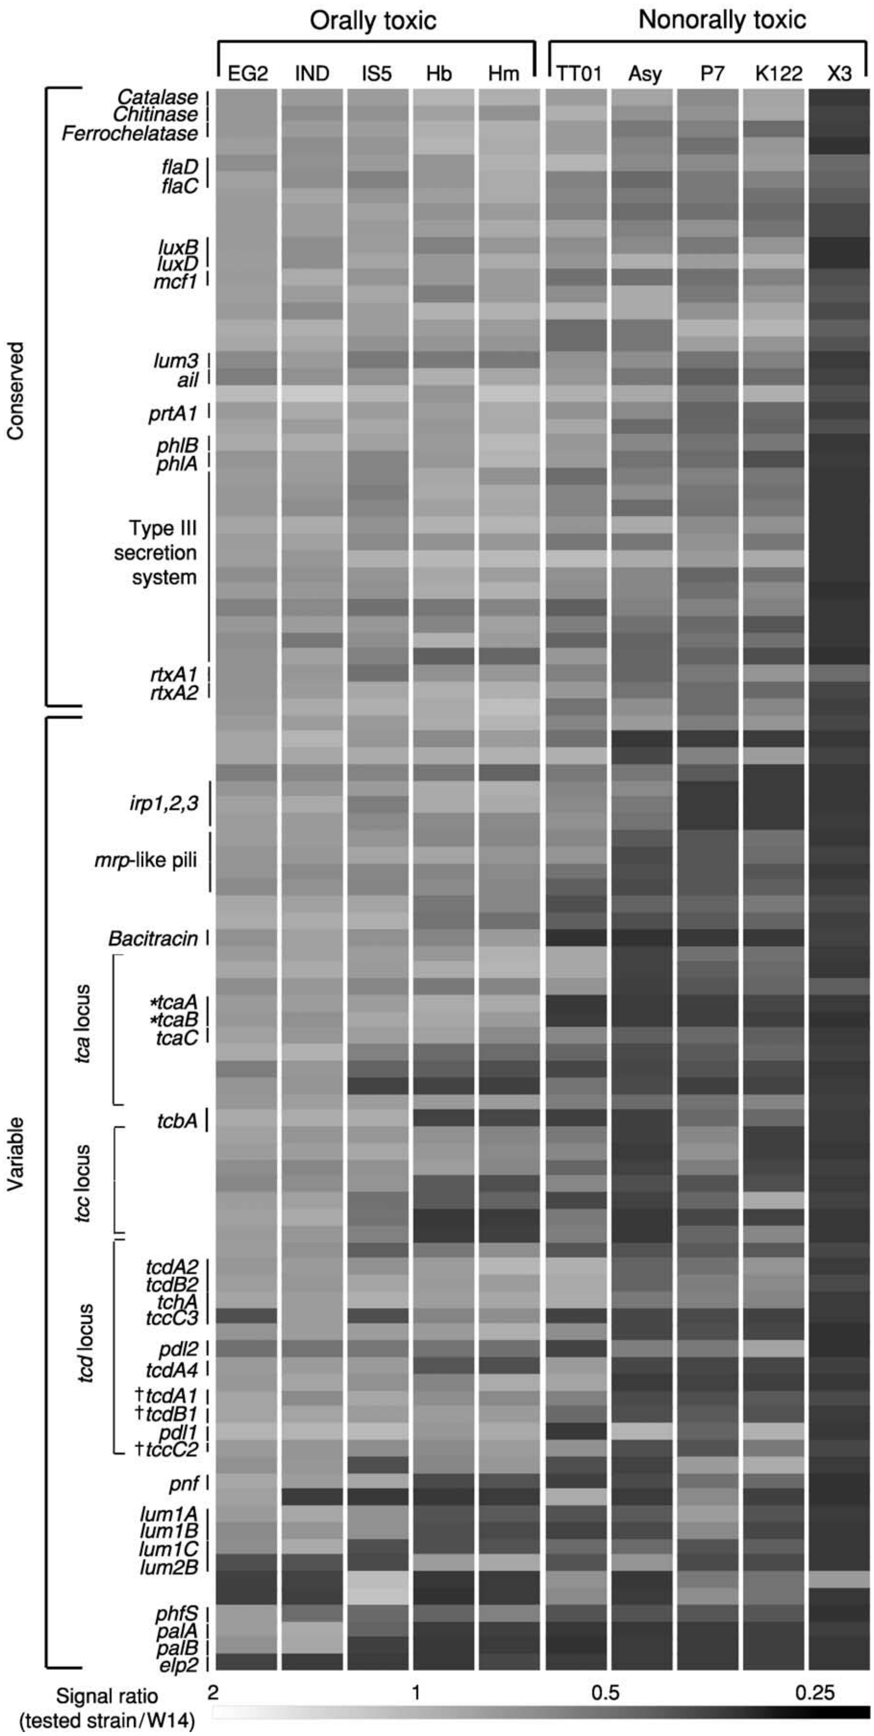

and genes involved in iron acquisition. Some toxin and hemolysin/hemagglutinin genes are also variable between strains. These include *pnf*, a *Photorhabdus necrotizing factor* that is found within a recently acquired region of the W14 genome (Waterfield *et al*., 2002) which is absent from TT01, and the *palA* and *palB* genes, encoding a hemolysin/hemagglutinin and its export activator (Waterfield *et al*., 2002). In W14, *palBA* is immediately downstream of the *mcf1* toxin gene and adjacent to a Phe tRNA (Waterfield *et al*., 2002) whereas in TT01 (**Figure 7**), *palBA* is deleted from the equivalent location, as predicted. In contrast, a second two-component hemolysin locus *phlAB* (Brillard *et al*., 2002), is predicted to be similar in all strains, and indeed potentially duplicated in strain Hm.

The *tc* genes correspond to variable genes, whose distribution is strikingly split between orally toxic and nontoxic strains (**Figure 11**). Orally toxic strains carry all three genes in the *tca* operon (*tcaA*, *tcaB*, and *tcaC*) whereas those lacking toxicity lack *tcaA* and *tcaB*. The genes of the *tca* operon are the only genes to show a perfect correlation with oral toxicity, and genes from *tcb, tcc*, and *tcd* are all variable across orally toxic strains. For the *tca* locus (**Figure 1**), a comparison of W14 and TT01 shows two important findings. First, the W14 *tcaABC* operon is absent from the equivalent location in TT01. Second, a *tca*-like locus is present elsewhere in TT01 but lacks most of *tcaA* and *tcaB*, which have been deleted, and retains only a *tcaC1*-like gene. These observations confirm that the presence of *tcaAB* is necessary for oral toxicity of the bacterial supernatant. Further, the fact that *tca*-like loci can be found at different locations in different genomes supports the concept that the *tca* locus is mobile, as suggested by the presence of either a transposase, in W14, or an integration protein, in TT01, adjacent to both *tca*-like loci (**Figure 1**). For the *tcb* locus, the suggestion that *tcbA* is lacking from TT01 is again confirmed by analysis of the genomic sequence, as *tcbA* is deleted from the equivalent location in TT01 and a transposase left in its place. Again comparing W14 and TT01, the array suggests that the *tcc* locus should be completely conserved, as supported by an examination of the genomic sequence. Finally for *tcd*, the genomic sequence (**Figure 3**) confirms that all the *tc* genes of the island are present in both W14 and TT01, including both *lysR*-like regulators. Further, the predicted loss of *tcdA4* in group 2 orally toxic strains is confirmed by an examination of this locus in the Hb strain. The array even predicts the loss of *pdl1* and *pdl2* from within the *tcd* island of TT01, again confirmed by the sequence (**Figure 3**). The localized deletion of *tcdA4*, and the apparent rearrangements mediated by *tccC*-like genes, again support the hypothesis that the *tcd* genes are encompassed in an unstable pathogenicity island. However, the consistent maintenance of four genetic elements within this island (*tcdA2, tcdB2*, a *gp13*-like holin, and the conserved region of *tccC3*), and the conserved organization of similar *tcd*-like genes in other bacteria (such as *sepA*, *sepB*, *orf4*, and *sepC* in *Serratia*), suggest that these genes form an invariant, but not orally toxic, core.

Previous analysis of strain W14 showed that either *tca* or *tcd* can independently contribute to oral toxicity. Thus plasmid clones of either *tca* or *tcd* from W14 confer recombinant oral toxicity when expressed in other nonorally toxic *Photorhabdus* strains, such as K122. This data is consistent with the current observation that the presence or absence of *tcaAB* is perfectly correlated with toxicity of the supernatant. However, all the *tc* genes within the *tcd* island are also present in some strains, such as TT01 (**Figure 3**), which lack orally toxic supernatants. To investigate the apparent lack of oral toxicity associated with *tcd* in TT01, the toxicity of the bacterial cells was examined independently of their supernatant and it was found that toxicity is associated with the cells rather than the supernatant (**Figure 12**). Confirmation that this novel cell-associated toxicity is *tcd* related now requires knockout or heterologous expression of this locus. In conclusion, even a very limited microarray can provide a powerful and predictive tool for correlating observed phenotypes with bacterial genotypes. Similar microarrays may therefore be useful in investigating other *Photorhabdus* phenotypes involved either in insect pathogenicity or symbiosis with their nematode hosts.

5.8.5. Conclusions

With the publication of the full genome sequence of strain TT01 and the ongoing sequencing of a *P. asymbiotica* strain at the Sanger Center, we are entering an era of comparative *Photorhabdus* genomics. As this review has indicated this now allows us to begin to determine where given toxin genes might have come from, and how they are passed between different strains. In the case of the *tc* genes, the appearance of orally toxic *tca* genes in divergent strains and the finding that these genes can occur at different locations in the genome support the hypothesis that they are mobile between strains. Microarray analysis of more toxin genes in a wider array of strains may also cast light on the origins of

other toxin genes such as *mcf1* and *mcf2*. Despite this recent explosion in sequence data, perhaps the most important biological questions remain largely unanswered. Thus, what is the biological role of the array of toxins that *Photorhabdus* encodes? Although it is easy to infer that these toxins may be necessary to kill the insect host, assessing the role of individual toxins via genetic knockout may be hampered by their functional redundancy. Thus, *tc* gene knockouts may show no oral activity but

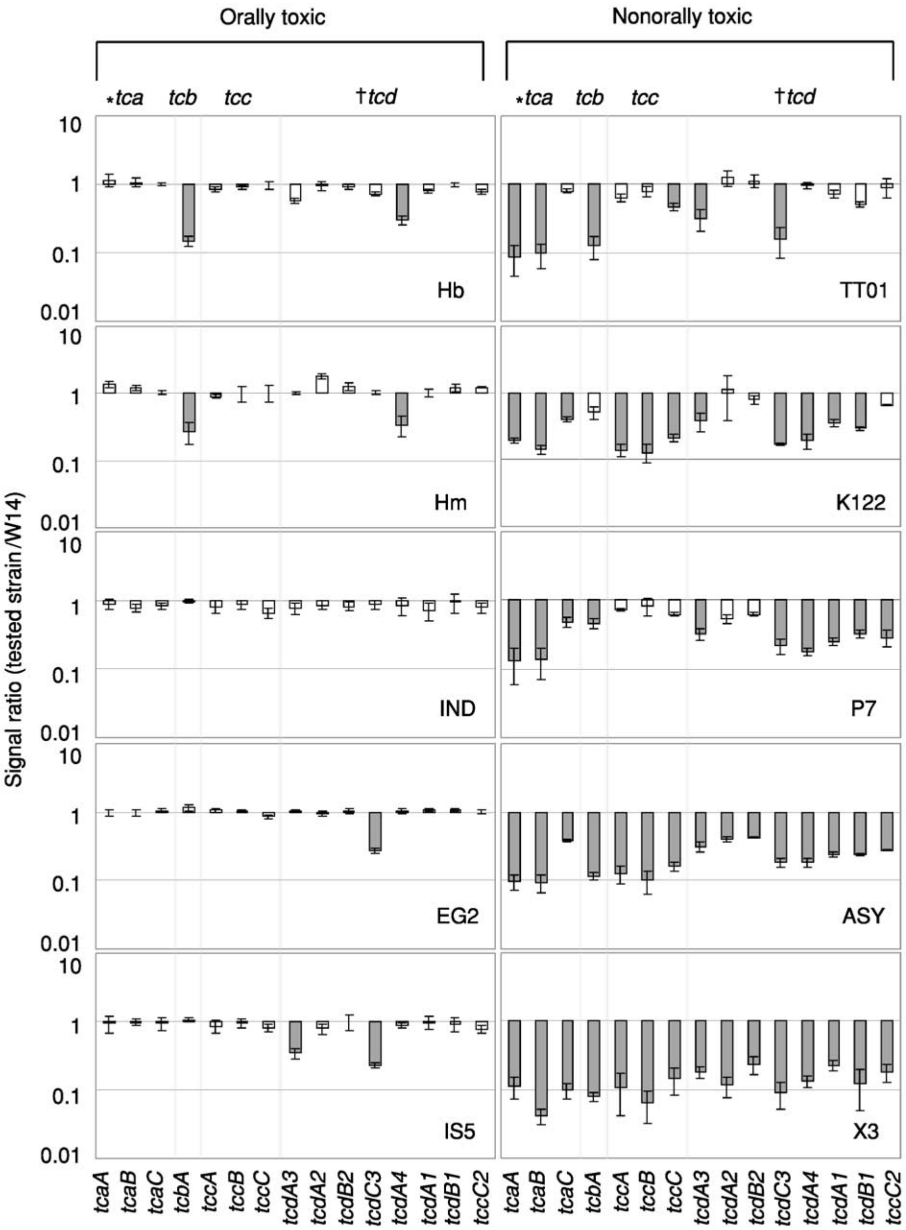

Figure 11 Detailed analysis of the array results for *tc* genes only. In this diagram ratios close to 1 predict the presence of a gene and ratios greater than 0.5 (shaded histograms) predict it to be absent. Note that only the presence of *tcaAB* (∗) is perfectly correlated with the presence of oral toxicity in the different strains (see text) and that *tcd* (†) is variable between strains.

Figure 10 Diagrammatic representation of microarray results where DNA from orally and nonorally toxic strains was hybridized to 96 W14 virulence factor genes. Genes have been divided into conserved (showing a consistent hybridization signal in all strains) and variable (those showing a variable signal between strains). Note for example that the type III secretion system appears present in all *Photorhabdus* strains, whereas members of the *tc* genes are variable (see text). The two loci implicated in oral toxicity are indicated: *tcaAB* (∗) and *tcdAB* (†).

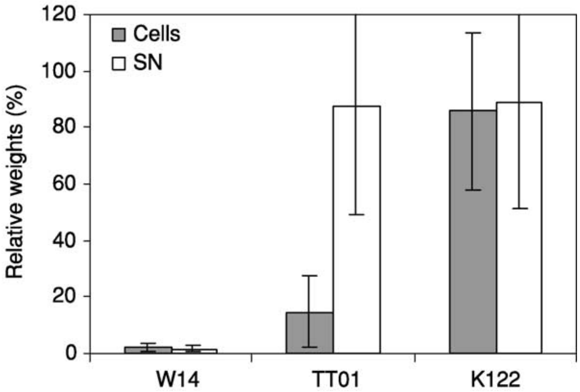

Figure 12 Comparison of supernatant (SN) versus cell-associated oral toxicity for three different *Photorhabdus* strains. Note that strain TT01 containing a complete copy of the *tcd* locus has no oral toxicity associated with the bacterial supernatant but does show oral toxicity associated with the bacterial cells (see text for discussion).

they can still kill the insect host. Further, mutants lacking *mcf1* take a longer time to kill insects but are still lethal. The current challenge is therefore to dissect out the individual roles of each toxin gene, even when they are members of large and rapidly growing gene families.

5.9.1. Introduction

5.9.1.1. Role of Amino Acid Transporters in Insects

Insects use amino acids as substrates for protein synthesis, as essential cofactors for intermediary metabolism, as intracellular messengers between distinct metabolic pathways, and as intercellular messengers – neurotransmitters. Amino acids are precursors in a variety of catabolic and anabolic pathways in which amino acid transporters serve as rate-limiting components (Saier, 2000a); e.g., glutamate transporters regulate the synthesis of GABA (Mathews and Diamond, 2003). In addition some insects use amino acids rather than glucose as an energy source (Balboni, 1978; Gade and Auerswald, 2002) and as osmolytes (Patrick and Bradley, 2000).

5.9.1.2. Uniporters, Symporters, and Antiporters

The movement of amino acids across membranes is catalyzed by transporters, which are polypeptides arranged as monomers or multimers. The collective interaction of these transporters with specific substrates and electrochemical driving forces generated by primary ATP-driven pumps and secondary mineral ion transporters is termed a "transport system" (Christensen, 1964; Gerencser and Stevens, 1994). Amino acid transporters fall into three groups on the basis of their electrochemical profiles: uniporters, symporters, and antiporters. Uniporters facilitate diffusion of amino acids down their own electrochemical gradients. Thermodynamically, uniporters are equivalent to channels but differ kinetically in possessing specific amino acid binding sites and lower conductances than inorganic ion channels. In contrast, amino acid:ion symporters (cotransporters) use electrochemical motive forces of inorganic ions for the translocation of amino acids, stoichiometrically coupled to the ions, usually inorganic cations or anions. A cotransporter can move an amino acid up its electrochemical gradient while the cotransported ion moves down its electrochemical gradient (the amino acid undergoes secondary active transport). Under specific conditions the coupling stoichiometry between amino acid and ion may change, resulting in a so-called "molecular slip" (Nelson *et al.*, 2002). In contrast to symporters, antiporters move thermodynamically coupled solutes in opposite directions and utilize different electrochemical mechanisms.

5.9.1.3. Energization and Electrochemistry of Amino Acid Uptake

The energization and electrochemical mechanisms of amino acid transporters vary greatly, depending upon the available electrochemical conditions (summarized in **Figure 1**). For example, classically characterized reuptake of neurotransmitters by high-affinity neurotransmitter transporters (NTTs) utilizes a steady-state Na^+ electrochemical gradient across neuronal membranes. The Na^+ gradient is thought to be generated by a Na^+/K^+ ATPase and the amino acid uptake is inhibited by agents, such as ouabain or vanadate, that inhibit Na^+/K^+ ATPase activity (Clark and Amara, 1993). More recently, it has become apparent that a proton-translocating, vacuolar-type ATPase (H^+ V-ATPase) has a dominant role in energization of membranes interfacing low sodium ion domains (Wieczorek *et al.*, 1999a). For example, it energizes processes in intracellular membranes (endomembranes), e.g., vesicular and lysosomal amino acid carriers. It serves as an essential energization component in synaptic vesicles, where it contributes to the hyperpolarization of the vesicular membrane and therefore facilitates Na^+-coupled reuptake of neurotransmitters (Nelson and Lill, 1994). Amino acid uptake mediated by transporters is also energized by V-ATPases in plasma membranes of cells exposed to media with low Na^+ concentrations, as in the midgut lumen of caterpillars and mosquito larvae (Harvey *et al.*, 1998). Nanomolar concentrations of bafilomycin or concanamycin inhibit the V-ATPase selectively (Drose *et al.*, 2001), providing a valuable pharmacological tool for the identification of V-ATPase-dependent carrier mechanisms.

Whether an amino acid is anionic (−), zwitterionic (+/−), or cationic (+) depends on the local pH and on amino acid dissociation constants. Other conditions being constant, the lower the pH the more protonated is the amino acid and the more positive is its charge. Conversely, the higher the pH the less protonated and the more negative is the amino acid. This dependence of charge transition upon pH value is especially important in mosquito larvae and caterpillars where amino acid uptake occurs through membranes with large electrostatic and pH gradients. Although the electrochemical interaction between H^+ V-ATPases and amino acid transporters in insect midgut is poorly explored, a tentative experimental model may be suggested by analogy with inorganic ion transporters, which mediate lumen alkalinization of caterpillar and mosquito larval midgut. One such component recruited in alkalinization is H^+ V-ATPase-energized Cl^-/HCO_3^- exchange, which was found in larval midgut of *Aedes aegypti* (Boudko *et al.*, 2001a). Alkalinization of anterior midgut and related pH gradients along the midgut lumen appear to be chiefly, if not exclusively, generated by transepithelial exchange of

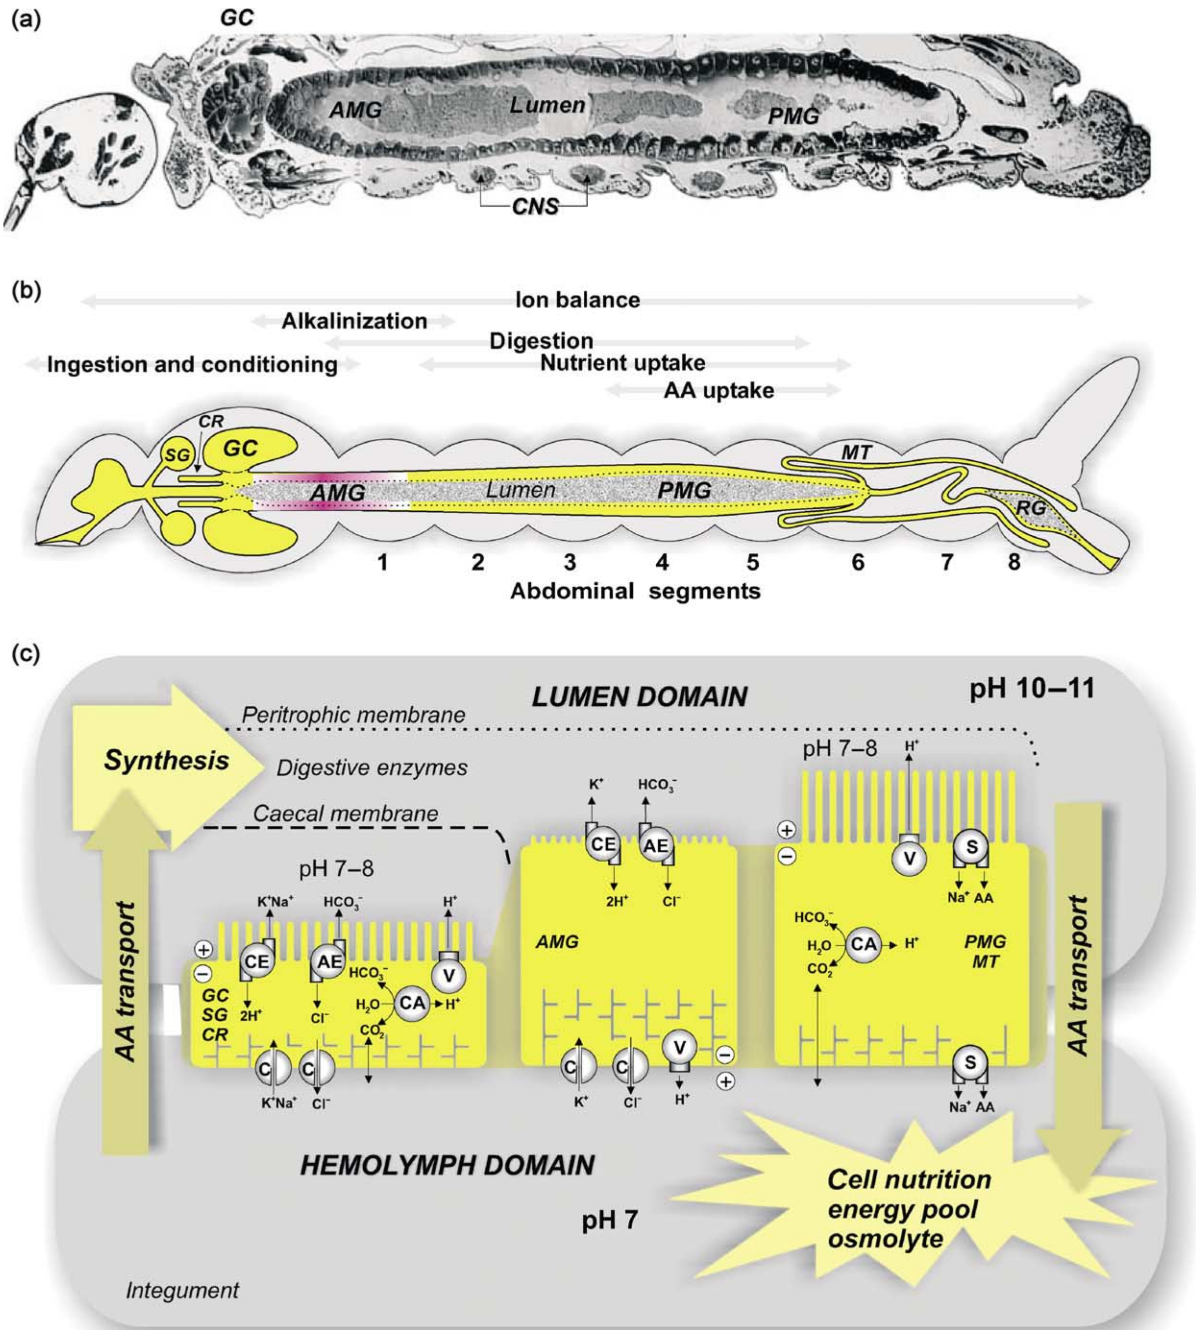

Figure 1 Energization and electrochemical mechanisms of amino acid uptake in insects (example from midgut of mosquito larvae). (a) Low magnification micrograph of longitudinal section showing general cytology of the larval midgut of 4th instar *Aedes aegypti*; (b) diagram illustrating distribution of specific physiological functions in alimentary canal of mosquito larvae; (c) simplified diagram showing putative electrochemical mechanisms that are involved in amino acid uptake in mosquito larvae. Abbreviations: AA, amino acids; AMG, anterior region of midgut; CR, cardia; CNS, central nervous system (ventral nerve cord ganglia); GC, gastric caeca; MT, Malpighian tubules; RG, rectal gland; PMG, posterior midgut; SG, salivary glands; S, symporter, V, H^+V-ATPase; C, channel; CE, cation exchanger; AE, anion exchanger; CA, carbonic anhydrase.

strong Cl^- and weak HCO_3^- anions that is energized by H^+ V-ATPases. So far no evidence for a significant role of Na^+/K^+ ATPases in energization of mosquito larval midgut cells has been obtained, but by analogy with known anionic pathways, a spatial exchange of strong inorganic cations and weak organic cations may mimic the role of Na^+/K^+ ATPases in generating the transmembrane Na^+ concentration gradients that are necessary for amino acid uptake. Alternatively, different motive

forces, e.g., for H^+, K^+, Cl^- as well as one for substrate itself can be used by nutrient amino acid transporters.

Since H^+ V-ATPase constantly moves protons from the cytosol to the exterior it renders the inside of its resident membrane negative to the outside, i.e., it strongly hyperpolarizes the resident membrane (Harvey, 1992). Due to electrical integrity of the insect midgut epithelia, both apical and basal membranes are hyperpolarized (Beyenbach, 2001). For example, even though the V-ATPase is resident on the apical plasma membranes of specific cells in posterior midgut of *Ae. aegypti* larvae (Zhuang *et al*., 1999), both membranes in such cells, as well as entire segments of posterior midgut epithelium, would be hyperpolarized relative to the lumen, implicating electrophoretic forces for charged amino acids and inorganic ions. Primary absorption of nutrient amino acids in posterior midgut of mosquito larvae (Clements, 1992) colocalizes with the residence and high activity of H^+ V-ATPases (Filippova *et al*., 1998; Zhuang *et al*., 1999; Boudko *et al*., 2001b). V-ATPases also colocalize with amino acid transporters in certain cells of the gastric caeca and cardia, where they appear to drive amino acid uptake from hemocoel to the cells (Boudko, unpublished data). These observations suggest that thermodynamic coupling between H^+ V-ATPases and amino acid transport mechanisms is widespread in insects. Significant correlations of H^+ V-ATPase expression and midgut invasion by malaria ookinetes has been reported in the Ross cells of adult *Anopheles gambiae* midgut (Cociancich *et al*., 1999). However, the role of V-ATPases in the infection mechanism remains to be clarified.

5.9.1.4. Structural Organization of Known Transporters

The physiological activity of most known amino acid transport systems is derived from transmembrane proteins that are monomers or form multimeric complexes within the plasma- and endomembranes. These proteins typically integrate 8–14 alpha-helical transmembrane spanning domains (TMDs) and a certain number of submembrane loops, which bear sites for interaction with the cytoskeleton and with other membrane and cytosolic proteins. Molecular identities of transport proteins have been explored mostly in mammals and, to some extent, in model insects (**Table 1**). In addition to monomeric transporters, there are several groups of unique transporters that act as obligatory heterodimers. For example, HAT heterodimers consist of a light chain, a catalytic subunit with 12–14 putative TMDs (SLC7), which is associated with a glycosylated globular heavy chain subunit that has only a single membrane spanning domain (SLC3) (see Section 5.9.7.2). Monomeric and heterodimeric transport systems appear in both nonpolarized cells and epithelial cells; however, they play different and most often complementary roles.

5.9.1.5. How Many Amino Acid Transporters Are Required?

Analysis of recently available genomes suggests that complex organisms require many transporters to regulate local amino acid concentrations in different tissues and cells. Due to their large size and ionic character, all amino acids require specific molecular carriers to pass lipid bilayers of cellular membranes. Mosquito larvae require 10 essential L-amino acids to reach the 2nd instar (Clements, 1992): three basic ones (arginine, lysine, and histidine) and seven neutral ones (valine, leucine, isoleucine, phenylalanine, tryptophan, threonine, and methionine). Thus, one would expect to find a subset of transporters for primary uptake of such amino acids through apical membranes in the posterior midgut as well as for their redistribution among specific body parts and tissues. Potentially, a single transporter gene may encode carriers for several amino acids with common structural features; however, several transporters would be necessary to reduce competition of amino acids for binding sites and to increase transport efficiency. A growing number of observations suggest that high-affinity uptake is required for a high degree of selectivity, implying that a large number of transporter phenotypes may exist. Nonessential amino acids, i.e., glycine, alanine, tyrosine, cysteine, serine, proline, aspartate, glutamate, and their derivatives, can be synthesized *de novo* within the insect organism. However, different tissues and cells have different requirements, often not matching nonessential amino acid anabolism. Hence, essential roles of transporters for nonessential amino acids have evolved and have become more prominent with increased tissue specialization and histological complexity of modern organisms. In addition to the population of plasma membrane amino acid transporters, a large number of specific transporters are necessary for translocation of amino acids between different intracellular domains. Moreover, insects undergo radical physiological and ecological transitions between larval and adult lifestyles. These transitions imply dramatic differences in amino acid requirements, which, together with certain requirements for genomic and phenotypic plasticity of amino acid transport mechanisms, may result in an increase of amino acid transporters being encoded. They may remain

inactive in insect genomes until activated, usually by a hormone, at a particular developmental stage.

5.9.1.6. Neurotransmitter Transporters and Nutrient Amino Acid Transporters

Amino acid transporters can be divided into two major categories with respect to their physiological roles: neurotransmitter transporters (NTTs) and nutrient amino acid transporters (NATs). Many phylogenetically distinct groups of amino acid transporters include both categories.

NTT denotes a carrier of neurotransmitters, which may be amino acids or their derivatives. Classical examples are plasma membrane insect NTTs for the high-affinity reuptake of glutamate, aspartate, glycine, and γ-aminobutyric acid (GABA), as well as the monoamines, dopamine, octopamine, 5-hydroxytryptamine (5-HT or serotonin), and histamine. Plasma membrane NTTs transport neurotransmitters from synaptic clefts into glial cells and presynaptic neurons. Intracellular NTTs serve for accumulation of neurotransmitters into synaptic vesicles, implicating them as one of the most critical components of presynaptic maturation for chemical signaling.

NAT denotes a carrier of one or more of the 20 natural α-amino acids with no apparent involvement in signaling processes, although there is weak background for such discrimination. Classical examples of insect NATs are those that absorb amino acids from the midgut or Malpighian tubule lumen through the apical membrane of specialized epithelial cells. NATs in the basal membrane export amino acids from epithelial cells into the hemolymph, comprising electrochemically different transport systems. Different NAT types are expressed in the basal cell membranes of the mosquito larval cardia, gastric caeca, and salivary glands, where they take up specific amino acids from the hemolymph and supply substrates for the synthesis of peritrophic and other secretory peptides. NATs in membranes of internal organelles participate in intermediary metabolism by supplying amino acids for metabolic pathways. Although glutamate, aspartate, and glycine transporters can be classified as NTTs or NATs, depending upon their role in specific cell types, in this review they will be discussed along with GABA transporters in Section 5.9.3.

A great deal is known about NATs in prokaryotes, yeast, and humans (Palacin *et al.*, 1998; Wipf *et al.*, 2002), but what little is known about them in insects is restricted mainly to caterpillars, fruit flies, and mosquitoes (discussed in Section 5.9.8.5.2). Much more is known about neurotransmitter amino acid transporters of insects (discussed immediately below and in Section 5.9.3).

5.9.2. Physiology of Insect NTTs

5.9.2.1. Synaptic Neurotransmission

The nervous system is responsible for the acquisition, integration, and storage of information. Neurons are specialized cells that enable electrochemical communication with each other, sensory cells, and target cells. This intercellular communication occurs predominantly at synapses, through the exocytotic release of chemical transmitters from the presynaptic neuron (Pennetta *et al.*, 1999; Caveney and Donly, 2002; Watson and Schurmann, 2002). Released transmitters diffuse across the synaptic space and bind to receptors on the postsynaptic membrane, resulting in either depolarization or other effects on the target cell (**Figure 2**). Transmitters are stored in the presynaptic terminal in vesicles, which are stocked with these chemicals by the action of transporters located in the vesicular membranes. The necessary stores of transmitter are acquired both through the biosynthesis of new molecules and the reuptake of released ones. Recovery of released transmitter is accomplished by transporters located in the plasma membranes of the various cells impinging on the synaptic space, both neuronal and glial cells (**Figure 2**). Thus, transport of neurotransmitters is important for the functioning of the synapse at two levels: for the packaging of transmitters in presynaptic vesicles prior to their release by exocytosis and for their reuptake from the extracellular space into the cytoplasm (Krantz *et al.*, 1999).

5.9.2.2. Role of Plasma Membrane NTTs in Synaptic Transmission

The action of released neurotransmitters is terminated by three major mechanisms: diffusion away from the synapse, buffering by the receptor and transporter ligand binding sites, and removal via uptake by high-affinity transporters present on neighboring membranes of presynaptic, postsynaptic, and glial cells (**Figure 2**). Much of the progress in understanding transmitter clearance has been carried out on various glutamatergic synapses in the mammalian CNS. Initially, diffusion was believed to play the predominant role in determining the concentration profile of glutamate in the synaptic cleft. In this view, plasma membrane transporters only act externally to the cleft – to lower extracellular glutamate levels, to contain the transmitter to the

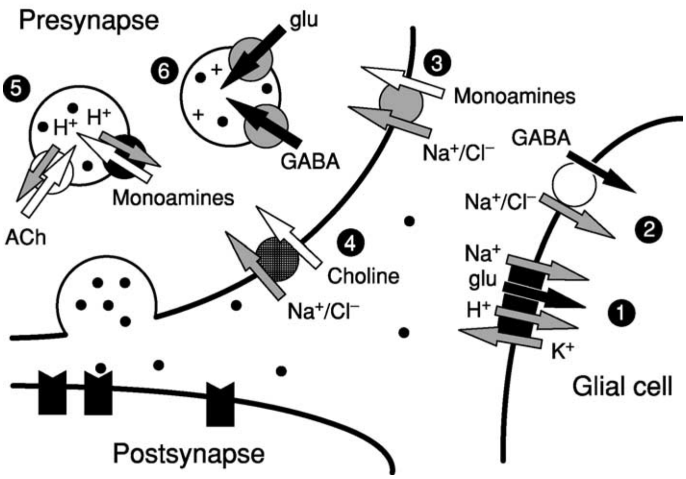

Figure 2 Neurotransmitters involved in insect synaptic signaling. Vesicles in the presynaptic neuron fuse with the presynaptic membrane and release neurotransmitters (•) that diffuse across the synaptic cleft and bind to receptors on the postsynaptic membrane. Unbound transmitters are taken up by various transport proteins in the plasma membranes of the presynaptic axon and adjacent glial cells: excitatory amino acid transporters (EAATs) that mediate Na^+ and K^+ dependent uptake of glutamate and aspartate into glutamatergic neurons or glial cells (1); and GABA and various monoamine transporters (SNFs) that mediate Na^+ and Cl^- dependent uptake of these ligands into glial cells (2) or back into neurons (3). A breakdown product of acetylcholine, choline, is transported into neurons by a different type of Na^+ and Cl^- dependent transporter that is related to glucose transporters (4). Neurotransmitters in neurons and glial cells are packaged into vesicles by transporters in the vesicular membrane, which are energized by proton/voltage gradients generated by the vacuolar H^+-ATPase. Transport of monoamines and acetylcholine into the vesicles is driven by a pH gradient (5), whereas transport of glutamate is driven by the electrical gradient (6). Vesicular GABA uptake is dependent on both gradients. Packaged neurotransmitters in neurons derived from this reuptake and from *de novo* synthesis are ready to be released when activated by an incoming voltage signal.

synapse, and to maintain a steep concentration gradient that promotes rapid diffusion (Krantz *et al*., 1999). Transporters were thought to play a limited role in the clearance of transmitter from the synapse. Moreover, because they cycle at very low speeds relative to receptor inactivation times, transporters were thought to affect only the slow components of glutamate removal (Otis *et al*., 1996). However, new data suggest that transporters play a dynamic role in the regulation of neurotransmission. For example, glutamate transporters may contribute to neurotransmitter inactivation on a rapid timescale. When present in high density, transporters may serve as binding sites without actually clearing the bound substrates (Seal and Amara, 1999). Also, Auger and Attwell (2000) found that glutamate removal by postsynaptic transporters at the climbing fiber synapse of rat Purkinje cells is very rapid, implying that translocation of glutamate may occur very early in the transport cycle. These observations suggest an active role for transporters in synaptic homeostasis, in which most of the presynaptically released transmitter is taken up rapidly and directly from the synapse. Other considerations affecting the relative roles of diffusion and uptake in regulating glutamate removal include the anatomy of individual synapses, with synapse diameter and the presence or absence of transporter-rich glia affecting the termination of postsynaptic excitation (Danbolt, 2001). Thus, the effects of diffusion and uptake on neurotransmitter concentration in the synaptic cleft depend upon the geometry of the cleft and adjacent spaces.

Analysis of amine transporter knockouts in mice also reveals a direct influence of transporters on the volume transmission of monoamines. Elimination of the relevant transporters revealed that by limiting neurotransmitter removal to diffusion alone, the extracellular transmitter concentration increased fivefold for dopamine, sixfold for serotonin, and twofold for norepinephrine (Gainetdinov and Caron, 2002; Torres *et al*., 2003). The persistence of dopamine in the extracellular space also increased 300-fold, relative to that in wild-type mice. Furthermore, intracellular transmitter concentrations were severely reduced, indicating reuptake is also crucial for the maintenance of the stores of these compounds. Therefore, the action of plasma membrane transporters is necessary for presynaptic homeostasis both for maintaining clearance kinetics and for providing adequate substrate levels.

Rapid removal of neurotransmitter from the synaptic cleft raises the prospect that transporter activity may influence the characteristics of postsynaptic

potentials, with broad implications for behavior and learning. However, this prospect has scarcely been explored.

5.9.2.3. Study of Insect NTTs

Much current knowledge on transporter structure and function has been derived from studies of vertebrate (particularly mammalian) examples. In general, transporters from insects are less well characterized than their vertebrate counterparts. However, several groups and even particular species of insect transporters are clearly orthologous to vertebrate transporters. Much of what is known of many of the specific categories of NTTs (from both a structural and functional perspective) have been inferred from discoveries in the mammalian CNS (reviews: Deken *et al*., 2002; Kanai *et al*., 2002; Torres *et al*., 2003). Commensurate with overall genome size, there appears to be less specialization in NTT complements in insects than in their mammalian equivalents. This relative simplicity may render NTTs promising targets for pest control as the insect nervous system possesses relatively less molecular redundancy to be overcome. The simplicity should also prove to make them tractable model systems for genetic and molecular dissection. Indeed, characterizing membrane transporters in the model organism *Drosophila melanogaster* has progressed rapidly and there has been significant progress in analyzing NTT transporters in Lepidoptera, as described below.

Insects may nevertheless provide a rich resource of NTT diversity, based on their extensive physiological variation and adaptation to diverse environments and lifestyles. In addition to the examples already identified by functional studies, the completion of the fruit fly and mosquito genomes has now allowed the entire complements of transporters from these two species to be categorized, as discussed below (Sections 5.9.5–5.9.9). Initial annotation of the *Drosophila* genome according to the gene ontology (GO) system resulted in the assignment of 665 transcripts within the "function" category as transporters (Adams *et al*., 2000). Comparison with the recently completed mosquito genome (Holt *et al*., 2002) has yielded further novel insights into insect transporters as well as a wealth of inferential insights based on comparison with the growing catalog of genomic databases (see Section 5.9.5).

5.9.2.4. Potential for Use of NTTs as Insecticide Targets

The importance of neurotransmitter reuptake at the synapse suggests that insect NTTs may serve as targets for insecticidal action. Many potent drugs that affect behavior by acting as "selective reuptake blockers" of plasma membrane NTTs have been identified in the mammalian brain (Torres *et al*., 2003). Gene knockouts (and antisense knockdowns) of various transporters in rodents have also demonstrated significant physiological consequences resulting from disruption of transporter function (Rothstein *et al*., 1996; Torres *et al*., 2003). In insects, the natural plant compound, cocaine, may exert behavioral and insecticidal effects through antagonism of the reuptake of amines in the nervous system, in particular that of octopamine (Nathanson *et al*., 1993). The role of GABAergic uptake activity in modulating behavior in *D. melanogaster* has been examined using a pharmacological approach (Leal and Neckameyer, 2002). Blocking GABA transporter function with reuptake inhibitors revealed specific effects on behavior including reduction of locomotor activity, geotactic abilities, and loss of the righting reflex. The specificity of the pharmacological effect to GABAergic activity was shown by the restoration of normal locomotor activity when inhibitors were applied in the presence of a GABA receptor antagonist. Thus, there is good reason to think that agents that block transporter activity may prove effective in perturbing pest behavior (by antifeedant or other insecticidal activities).

5.9.3. Molecular Biology of Insect NTTs

5.9.3.1. Classification of NTTs

The increasing availability of genomic information now allows a holistic approach to the analysis of the structure and function of specific transporters. By comparing complete genome complements of protein components in diverse organisms, it is possible to develop hierarchies based on structural conservation reflecting biological themes that have evolved in response to functional requirements. For membrane proteins that transport amino acids, a comparison of three sequenced eukaryotic genomes (*Saccharomyces cerevisiae*, *Arabidopsis thaliana*, and *Homo sapiens*) distinguished five different transporter superfamilies based on phylogeny, substrate spectrum, transport mechanism, and cell specificity (Wipf *et al*., 2002). An even more comprehensive scheme has been devised by Saier (2000b) to classify all permeases based on both phylogeny and function. The resulting transporter classification (TC) system uses five criteria to group individual transporters within each family. Transporters in the nervous system belong to six separate

families in the TC system (**Table 1**). The primary distinction demarcating the various nervous system transporters is the site at which the transport system is active. Plasma membrane transporters transfer released neurotransmitter from the synaptic space back into the cytoplasm of neurons and glial cells using the inwardly directed Na^+ gradient across the plasma membrane (Masson *et al.*, 1999). Vesicular transporters located in neuronal synaptic vesicles further concentrate transmitters from the cytoplasm inside the vesicles using proton electrochemical gradients generated by the vacuolar type H^+-ATPase (Yelin and Schuldiner, 2002).

5.9.3.2. Plasma Membrane Neurotransmitter Transporters

It has long been recognized that nervous tissues are capable of taking up a variety of endogenous substrates by way of specific, high-affinity, Na^+-dependent plasma membrane transport. The energy for this uptake derives from coupling the inward transport of neurotransmitter to the flow of sodium ions, using the inwardly directed electrochemical Na^+ gradient generated by the Na^+/K^+-ATPase (see Section 5.9.1.3). The molecular identities of the membrane proteins responsible have become known over the last 10–15 years, revealing structural similarities to at least three families of transporters (**Table 1**; Krantz *et al.*, 1999). Members of the excitatory amino acid transporter (EAAT) family (for glutamate and aspartate) are distinguished by the counter-transport of potassium ions, and this group includes other members that transport neutral amino acids as substrate. Proteins in the sodium neurotransmitter symporter family (SNF) are characterized by 12 transmembrane domains and depend upon chloride for uptake activity. This family is made up of four subfamilies, encompassing a variety of substrates ranging from various amino acids to amines. Finally, the most recently characterized family is the glucose transporter family, which includes carriers for choline. All three of these families also include many other more distantly related prokaryotic transporters. A new classification scheme of insect SNF transporters is proposed in Section 5.9.8.5.

5.9.3.3. Excitatory Amino Acid Transporters (EAAT; SLC1)

5.9.3.3.1. Roles of glutamate and EAATs in insects L-Glutamate has been implicated in many important physiological processes in mammals including neuronal development, plasticity, and long-term potentiation, as well as in pathological conditions including epilepsy, cerebral ischemia, amyotrophic lateral sclerosis, Alzheimer's disease, Parkinson's disease, and schizophrenia (Danbolt, 2001). L-Glutamate also is the most abundant amino acid in the insect CNS, acting as both an excitatory and an inhibitory neurotransmitter (Bicker *et al.*, 1988; Usherwood, 1994) via high-affinity binding/activation of postsynaptic receptors, which are classified as metabotropic and ionotropic subtypes (Monaghan *et al.*, 1989; Gasic and Hollmann, 1992). It also acts as the principal excitatory transmitter at neuromuscular junctions (Jan and Jan, 1976a, 1976b) binding to specific receptors on somatic muscles (Schuster *et al.*, 1991; Petersen *et al.*, 1997). Whereas, essential roles of glutamate in the insect CNS have been deduced from extensive immunohistochemical labeling of the ligand, its receptors, and transporters, its physiological roles, as well as their central mechanisms, remain poorly understood. Apparently, brain-specific glutamate in insects mimics processes known in the mammalian CNS, including afferent signaling and memory; e.g., it appears to mediate central mechanisms that are associated with long-term olfactory memory in the honeybee (Maleszka *et al.*, 2000), and to mediate *N*-methyl-D-aspartate (NMDA) type glutamate receptor-coupled regulatory pathways in the biosynthesis of juvenile hormone (Chiang *et al.*, 2002). Moreover, little is known about the physiology of glutamatergic transmission and glutamate/aspartate excitotoxicity in insects.

5.9.3.3.2. Insect EAATs Transporters of glutamate in the nervous system have recently been cloned and characterized from several insect species. The isolation of these genes was based on sequence similarities with vertebrate EAATs, using PCR with degenerate primers: sequence comparisons showed them to be members of this distinct family of transporters (dicarboxylate/amino acid:cation (Na^+ or H^+) symporter family by Saier, 2000b (TC 2.A.23); **Table 1**). This group corresponds to the mammalian solute ligand carrier group 1 (SLC1). Cloned insect EAATs comprise two from fruit flies (Seal *et al.*, 1998; Besson *et al.*, 1999), one from caterpillars (Donly *et al.*, 1997), one from cockroaches (Donly *et al.*, 2000), one from yellow fever mosquitoes (Umesh *et al.*, 2003), and one from honeybees (Kucharski *et al.*, 2000). They share up to 45% protein sequence identity and common secondary structures, which are characterized by six putative alpha-helical transmembrane domains and 2–4 beta-pleated domains resembling the beta-barrel structures of pore-forming ion channels (Seal *et al.*, 1998). Demonstrated substrates for these

insect EAATs include glutamate and also aspartate, which may sometimes act as a cotransmitter with glutamate. Biophysical studies with vertebrate transporters have shown that the transport of these substrates is electrogenic, involving the uptake of one amino acid$^-$ anion coupled to the cotransport of three Na^+ cations, one H^+ cation, and the countertransport of one K^+ cation (net inward flux of two positive charges per cycle). A novel property of vertebrate EAATs is the possession of a substrate-gated anion channel activity, as suggested by the presence of channel-like structures in the C-terminal portion of the protein. *Drosophila* EAAT1 protein expressed in frog oocytes induces a chloride flux that is consistent with this postulated channel-like activity (Seal *et al.*, 1998).

In situ hybridization detected the expression of both dmEAAT1 and dmEAAT2 in neuronal cells, however with distinct patterns for each transcript (Besson *et al.*, 1999). Similar extensive expression of EAAT has been detected in adult brain of the honeybee *Apis mellifera*, where it was associated with the mushroom bodies in which glial cells are rare (Kucharski *et al.*, 2000). In contrast, *in situ* hybridization, using *Trichoplusia ni* EAAT cDNA probes on whole mount caterpillar ganglia, identified a population of interfacial glial cells (Caveney and Donly, 2002). An immunohistochemical analysis on EAAT localization using antipeptide antibodies raised against the *T. ni* EAAT amino acid sequence produced selective staining in the ganglionic neuropil, as well as extensions of glial sheath cells wrapped around nerve processes that innervate skeletal muscles (Gardiner *et al.*, 2002). In contrast, an antipeptide antibody raised against the *A. aegypti* EAAT stained only the thoracic ganglia and not the muscles (Umesh *et al.*, 2003).

Comparisons between insect and vertebrate EAATs, based on structure, pharmacology, or expression, have failed to indicate clearly to which classes of vertebrate EAATs the insect transporters belong (Donly *et al.*, 1997; Seal *et al.*, 1998; Kucharski *et al.*, 2000). Most unexpected is the strong preference of fruit fly EAAT2 for aspartate as a substrate (Besson *et al.*, 2000). Sequence comparison among insect EAATs (**Figure 3**), reveals a cluster of putative aspartate transporters with similarity to the fruit fly EAAT2. Among the remaining glutamate transporters in the tree, there is no pattern relating to localization of expression, as there are examples of expression in both glial cells and neurons (drmEAAT1 is neuronal whereas trnEAAT is glial). Several putative EAATs (also compared in **Figure 3**) are derived from the recently completed mosquito (*A. gambiae*) genome and an early

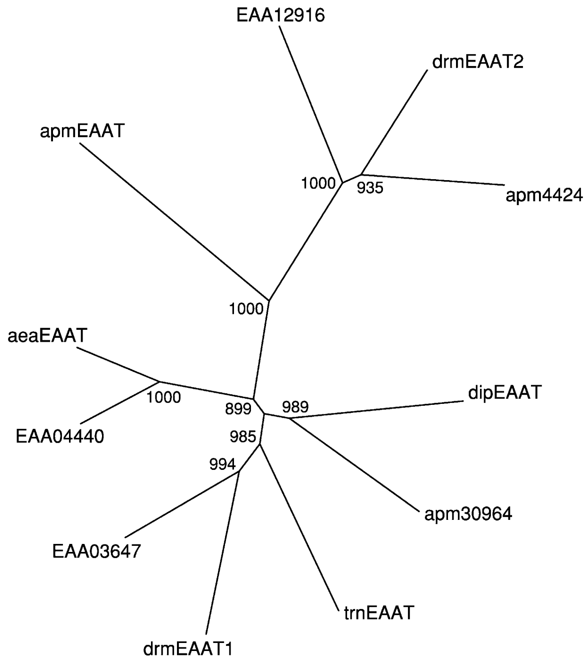

Figure 3 Dendrogram/bootstrap analysis of insect excitatory amino acid transporters. Sequence similarity was assessed using amino acid alignments in Clustal X 1.81 (Thompson *et al.*, 1997) and an unrooted tree was calculated by the ''neighbor joining'' method. Confidence values were derived by ''bootstrapping'' the dataset, using 1000 replicates and a generator seed value of 333 (Clustal X 1.81). The alignment was visualized using Treeview 1.6.6 (Page, 1996). The variable N- and C-terminal regions of the amino acid sequences were trimmed so that the region used for comparison extended from the first to the last predicted transmembrane domains. The accession numbers for the characterized transporters are found in **Table 1**. The three putative *Anopheles gambiae* EAAT sequences have accession numbers EAA12916, EAA04440, and EAA03647 as marked. The two putative honeybee EAAT sequences (in addition to the known apmEAAT) were deduced from contigs 30964 and 4424 from the initial assembly of the *A. mellifera* genome (Baylor Human Genome Sequencing Center).

assembly of the honeybee (*Ap. mellifera*) genome. Both genomes contain evidence for at least three potential EAATs. In contrast, the fruit fly genome contains only two EAATs. Based on this difference in EAAT complement between two related dipteran species, it seems possible that significant variability in EAAT complements may exist across the breadth of the Insecta.

5.9.3.4. Na^+/Cl^--Driven Neurotransmitter Symporters (SNF; SLC6)

The essential role of neurotransmitter uptake in synaptic transmission and integrative nerve function was established long before the cloning of the first transporter (Levi and Raiteri, 1974). The existence of a family of plasma membrane transporters that is responsible for Na^+ and Cl^--dependent transport in

the nervous system first became apparent when similarity was observed between two mammalian transporter cDNAs that were isolated based on protein purification and sequencing (Guastella *et al.*, 1990; Liu *et al.*, 1992a) and on expression cloning (Pacholczyk *et al.*, 1991). The similarity between these two transporters, one for GABA and the other for norepinephrine, was subsequently used to isolate a variety of other transporters in many organisms (including insects), which transport diverse substrates in the nervous system and other tissues. These transporters make up the Sodium Neurotransmitter Symporter family (SNF), which corresponds to the mammalian solute carrier group, SLC6 (TC 2.A.22; **Table 1**). All such transporters possess common features of structure and function, but nevertheless exhibit remarkable differences in their interaction with transmembrane electrochemical gradients for Na^+, K^+, and Cl^- as well as substrate selectivity, affinity, and carrier capacity. Protein sequence hydrophobicity and conformation profiles predict quite similar 12-TMD structures for these transporters, with cytosolic N- and C-terminals and an extended extracellular loop between TMDs 3 and 4 having a variable number of *N*-glycosylation sites (see Section 5.9.8.5).

Sequence comparison among vertebrate neurotransmitter transporters reveals five orthologous clusters among family members that can be defined according to substrate specificity as: (1) inhibitory neurotransmitter transporters for GABA and glycine; (2) aminergic neurotransmitter transporters for norepinephrine, serotonin, and dopamine; (3) the osmolyte transporters for betaine and taurine; (4) metabolic intermediate creatine transporters; and (5) amino acid transporters for proline and glycine (B^{0+} system). In addition, mammalian members of this family include several groups of "orphan" transporters for which no substrates and functions are yet known (Chen *et al.*, 2003; Lill and Nelson, 1998). Comparison of the amino acid sequences of insect examples also reveals orthologous clustering, however differences from the vertebrate results are evident (**Figures 4, 6,** and **10**). Phylogenetic analyses show very clear differences between two large clusters of insect SNF members (**Figures 6** and **10**), which can be defined as Neurotransmitter Transporters (NTTs) and nutrient amino acid transporters (NATs) based also on their functional characteristics, which have been determined for many cloned insect transporters (see discussion below and Section 5.9.8.5.2, respectively). Due to their clear functional and phylogenetic specificity, these clusters represent a first and most significant divergence within the insect SNF; these clusters can reasonably be defined as NTT and NAT subfamilies. In addition, most insect NTTs form orthologous pairings with mammalian complements mentioned above, as well as sharing substrate and physiological roles in neuronal signaling, each of which has been confirmed for at least one cloned and characterized insect transporter. Despite their phylogenetic proximity to B^{0+} transporters, insect NATs encompass no substantial correlations in ligand specificity to such mammalian transporters. In contrast, they represent a large and lineage-specific (paralogous) group of NATs, which apparently are absent in the mammals and some other lineages (see discussion in Section 5.9.8.5.2).

5.9.3.4.1. GABA transporters As in the vertebrate CNS, GABA serves as the primary inhibitory neurotransmitter in the insect nervous system (Callec, 1985). Immunocytochemical studies of GABAergic transmission sites using antibodies against GABA, glutamic acid decarboxylase (the essential enzyme for GABA synthesis), and various GABA receptor subunits have revealed an extensive pattern of GABA activity in the nervous systems of a variety of insect species. This pattern implies roles for GABA in diverse processes including visual and olfactory processing, as well as learning and memory (reviews: in Caveney and Donly, 2002; Umesh and Gill, 2002). The main mechanism by which GABA activity is terminated on the postsynaptic membrane is through reuptake into neurons and glial cells by high-affinity transporters (Callec, 1985). High-affinity insect GABA transporters (GATs) have been cloned and characterized from the hawkmoth, *Manduca sexta* (Mbungu *et al.*, 1995) and the cabbage looper, *T. ni* (Gao *et al.*, 1999). In each species, Northern analysis was used to localize expression of a single observed mRNA transcript to the nervous system. The hawkmoth masGAT protein has also been further localized by immunocytochemistry (Umesh and Gill, 2002). The results indicated that transporter immunoreactivity coincides closely with previously determined patterns of GABAergic activity, including staining of brain areas involved in processing visual and olfactory information.

The two characterized lepidopteran GATs show ionic stoichiometry and kinetics similar to those of the vertebrate GAT1 subtype (Mbungu *et al.*, 1995; Gao *et al.*, 1999). However, the pharmacological profiles of the lepidopteran transporters are distinct from any known vertebrate subtype, particularly in their insensitivity to several nipecotic acid derivatives, which are potent inhibitors of GAT1. Only one GAT has been found in each moth species; in

contrast, vertebrates exhibit diversity at two levels. First, the vertebrate GATs, which in the rat are enumerated as GATs 1–3, display unique cellular expression patterns and affinities for GABA. Second, various related transporters have been identified in vertebrates, showing affinities for other substrates including taurine, creatine, and betaine. The presence of multiple GATs has been reported in *Drosophila* (Neckameyer, 1998), which is in contrast to the apparently unified phenotype studied in two lepidopteran models (Mbungu *et al.*, 1995; Gao *et al.*, 1999). Analysis of the fruit fly and mosquito genomes shows that each contains only a single GAT locus (at least of the known Na^+- and Cl^--dependent type). Consequently, any diversity in GAT transcripts or proteins must result from alternative splicing of a single gene. In addition, no genes or transcripts that appear to encode taurine or creatine transporters have been identified in insects to date.

5.9.3.4.2. Monoamine transporters Monoamines that serve as neurotransmitters in insects include serotonin (5-HT), dopamine, octopamine, and histamine (Monastirioti, 1999). The neuroactive amines in insects differ from those of vertebrates in that octopamine appears to substitute functionally for norepinephrine in insects. Tyramine, the immediate precursor of octopamine, may also have a role in neurotransmission but its status has remained controversial. Recently, tyramine was shown to be the effective ligand of the fruit fly amine receptor (TyrR) in modifying larval neuromuscular junction potentials, producing new evidence for a role for tyramine as a neuromodulator (Nagaya *et al.*, 2002). Monoamines play diverse roles in insect behavior and physiology, acting in the nervous system as well as in many peripheral tissues. In the nervous system, serotonin, dopamine, and octopamine are slow-acting neurotransmitters that bind to G protein-coupled receptors and modulate various second messengers, such as cyclic nucleotides and Ca^{2+}. After being released, they are taken up by high-affinity transporters for reuse or inactivation by N-acetylation. Transporters for all three of these monoamines are present in insects, clustering according to their transport substrate in sequence comparisons of insect Na^+/ Cl^--dependent transporters (**Figures 4, 6,** and 10).

5.9.3.4.2.1. Serotonin transporter (SERT; 5HTT) Indolamine uptake activity in the insect nervous system was first demonstrated in nerve fibers of the locust brain (Klemm and Schneider, 1975), followed by the finding of high-affinity serotonin

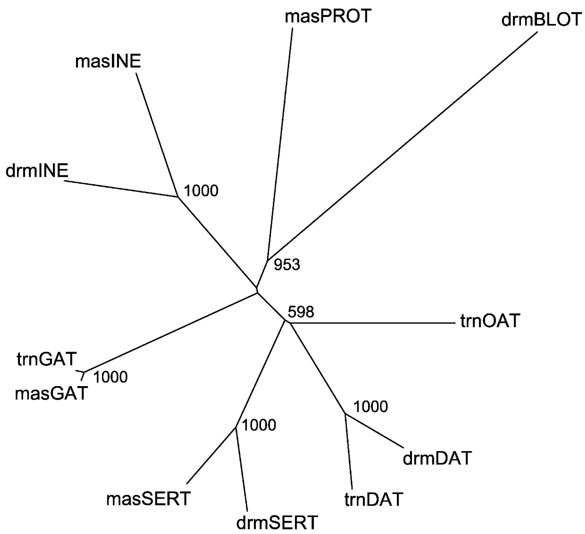

Figure 4 Dendrogram/bootstrap analysis of insect nervous system Na^+/Cl^- dependent neurotransmitter transporters. The sequences used were limited to those for which there is a characterized insect example published (accession numbers are listed in **Table 1**). The comparison was performed as in **Figure 3**, using amino acid sequences trimmed to the first and last predicted transmembrane domains.

transport activity in many other insect species. In insects serotonin is also involved in neuromuscular transmission (McDonald, 1975) and epithelial transport processes, such as fluid balance (Maddrell, 1962; O'Donnell and Maddrell, 1984; Brown and Nestler, 1985), as well as in modulation of acid/base balance and midgut alkalinization (D. Boudko, unpublished data). It also serves in the integration of complex behavior patterns in insects, including aggression and defense (Baier *et al.*, 2002; Kostowski *et al.*, 1975), feeding (Novak and Rowley, 1994) and mating arousal (Yellman *et al.*, 1997), circadian rhythms (Muszynska-Pytel and Cymboroski, 1978a; Muzynska-Pytel and Cymborowski, 1978b), and memory (Carew, 1996). The first insect serotonin transporter cDNA (dSERT) to be cloned and characterized was that from *D. melanogaster* (Corey *et al.*, 1994; Demchyshyn *et al.*, 1994). The fruit fly transporter has pharmacological properties that are distinct from those of mammalian SERTs, such as a much lower sensitivity to antidepressant antagonists. A SERT that was recently cloned and characterized from the hawkmoth, *M. sexta*, was less sensitive to cocaine binding than other SERTs (Sandhu *et al.*, 2002b). Structural modification of the cocaine-sensitive human SERT, by using chimeras that mimic fragments of the insect molecule, revealed important elements involved in the interaction with cocaine (Sandhu *et al.*, 2002b). This finding is relevant for human health and

important for understanding serotonin transporter biology; it also illustrates the value of arthropod models in uncovering structure– function relationships of complex transport proteins through comparative studies. Serotonin transporters are represented by a single gene in the *D. melanogaster* genome and apparently in the *An. gambiae* genome as well. Two conceptual translation entries seen in NCBI (EAA05837 and EAA03384) are identical by nucleotide sequence and have yet to be mapped, which together suggest that they may be fragments of a single gene copy (**Figure 6**).

5.9.3.4.2.2. Dopamine transporter (DAT) Dopamine is the most abundant catecholamine in the insect nervous system, with dopamine-containing neurons being widely distributed throughout a variety of species (Osborne, 1996). In contrast, only trace quantities of the vertebrate catecholamine transmitter, norepinephrine, can be detected in the insect nervous system. Dopaminergic neurons modulate both visceral and skeletal muscle activity, with dopamine affecting flight motor patterns in *M. sexta* and the escape circuit in cockroaches (Osborne, 1996). Dopamine release from peripheral nerve endings also stimulates salivary gland secretions in many species. The first insect dopamine transporter (DAT) was cloned and characterized from the fruit fly (Porzgen *et al.*, 2001). This transporter exhibited substrate selectivity similar to vertebrate DATs (dopamine and tyramine are preferred substrates), but showed a distinct pharmacological profile that is reminiscent of mammalian norepinephrine transporters (with high affinities for tricyclic antidepressants). A second DAT, isolated from the cabbage looper moth, has similar properties (Gallant *et al.*, 2003). These transporters cluster closely, along with another putative DAT sequence that is present in the mosquito genome (**Figures 4, 6, and 10**). It has been proposed that these invertebrate DATs represent conserved copies of a primordial catecholamine transporter that existed before the divergence of mammalian catecholamine carriers into subtypes responsible for dopamine and norepinephrine uptake (Porzgen *et al.*, 2001).

5.9.3.4.2.3. Octopamine transporter (OAT) Octopamine is the monohydroxylic analog of norepinephrine in insects. It is present in high concentrations in a range of insect tissues including the nervous system, where it may act as a neurotransmitter, neurohormone, and neuromodulator (Roeder, 1999). It modulates afferent and efferent signaling in locusts (Homberg, 2002; Leitch *et al.*, 2003). Na^+-dependent (and independent) octopamine uptake has been reported in various cockroach tissues (Sinakevitch *et al.*, 1994) and firefly lantern (Robertson and Carlson, 1976; Copeland and Robertson, 1982). In the honeybee, it mediates consolidation of olfactory memory (Farooqui *et al.*, 2003) and hygienic behavior (Spivak *et al.*, 2003) as well as complex social behavior, including labor establishment (Schulz *et al.*, 2002). Despite abundant neurotransmitter roles for octopamine, examination of the completed dipteran genomes reveals no alternative genes that may encode a Na^+/Cl^--dependent transporter for octopamine uptake. In these insects, it has been proposed that octopamine may be dispersed by an alternate mechanism, or perhaps taken up by a member of an unrelated transporter family (Porzgen *et al.*, 2001). Nevertheless, a novel transporter cDNA that was isolated and cloned from the lepidopteran *T. ni*, using RT-PCR with degenerate primers, showed remarkable sequence similarity to DAT transporters (Malutan *et al.*, 2002). However, this transporter is distinct from known DATs in that it has a high affinity for octopamine along with tyramine and dopamine; in addition it is expressed in a different subset of neuronal cells in the caterpillar nervous system than DAT. This octopamine transporter (OAT) showed relaxed ionic dependency relative to other insect monoamine transporters and was generally resistant to pharmacological inhibitors of monoamine transporters. Comparison of the OAT sequence with other Na^+/Cl^--dependent transporters shows that it clusters with mammalian norepinephrine transporters but not other insect transporters, including those for monoamines (**Figures 6 and 10**). OAT emerges almost equidistant from the serotonin and dopamine transporter branches in a high-resolution dendrogram (**Figure 4**). The extent to which this novel type of transporter is distributed among insect orders remains to be determined.

Finally, most of the histamine in the insect nervous system is in the retina and optic lamina, where it functions as an inhibitory neurotransmitter (Stuart, 1999). However, searches for a histamine transporter based on expected homology to other monoamine transporters have detected no putative candidates. This failure may indicate that the histamine transporter is a member of a novel or unrelated transporter family, as in the case of the delayed discovery of transporters for choline in the nervous system (see Section 5.9.3.5). Alternatively, functional screening may yet identify a histamine transporter.

5.9.3.4.3. Glycine and proline transporters In vertebrates, a distinct subfamily of Na^+/Cl^--dependent NTTs transports the amino acids glycine (GLYT)

and proline (PROT) (Deken *et al*., 2002). Multiple subtypes of transporters for the inhibitory amino acid glycine are expressed both in the CNS and in peripheral tissues. Although arthropods apparently lack receptors for glycine (Witte *et al*., 2002), sequence comparison with vertebrate GLYTs reveals potential Gly type transporters in both the *D. melanogaster* and *An. gambiae* genomes (CG5549 or NP_611836 and EAA07088, respectively). Vertebrates have only a single high-affinity proline transporter type (it is brain specific), which is thought to be associated with modulating activity at glutamatergic synapses (Deken *et al*., 2002). In insects, proline is an alternative energy source and major osmolyte, but its role in the nervous system remains unproven. Nevertheless, a Na^+/Cl^--dependent proline transporter was recently cloned from *M. Sexta*, where it is predominantly expressed in the nervous system (Sandhu *et al*., 2002a). This protein transported proline exclusively when heterologously expressed in *Xenopus* oocytes. Sequence comparison shows that the hawkmoth PROT is related to known vertebrate glycine and proline transporters (Sandhu *et al*., 2002a). The *D. melanogaster* and *An. gambiae* genomes also each contain a related sequence (CG7075 or NP_723303 and EAA12299, respectively) representing putative orthologs. Moreover, two gene products that apparently represent alternative splicoforms of a single gene in the 2L chromosome are present in *D. melanogaster* expressed sequence tags (ESTs for NP_723303 and NP_609135, **Figure 6**).

5.9.3.4.4. Orphan inebriated (ine) and bloated tubules (blot) transporters The identification of Na^+/Cl^--dependent transporter family members based on structural similarity has resulted in the discovery of many putative transporters for which the substrates are not known. Many of these so-called “orphan” transporters are larger than other Na^+/Cl^--dependent transporters, with extended fourth and sixth extracellular loops and a larger C-terminus. The expression patterns of these orphan transporters are often diverse, with extensive nervous system and peripheral distributions. Insect examples include the *Drosophila* blot (bloated tubules) and *ine* (inebriated) proteins, and the *M. sexta ine* protein (ms*ine*). The “inebriated” locus, relating to a characteristic “inebriated” behavior phenotype (Stern and Ganetzky, 1992) was initially cloned from *D. melanogaster* and its expression was mapped by *in situ* hybridization in the posterior hindgut, Malpighian tubules, anal plate, garland cells, and a subset of cells in the CNS of developing embryos (Soehnge *et al*., 1996). It has been proposed by analogy with other NTTs that the neuronal hyper-excitability characteristic of the *ine* phenotype is a result of failure in some neurotransmitter uptake due to *ine* mutations (Soehnge *et al*., 1996); however, the identity of any such ligands remains elusive. Additional transgenic characterization led to the hypothesis that a neuronal dm*ine* isoform mediates downregulation of sodium channels via a neurotransmitter uptake (Huang and Stern, 2002) whereas an epithelial dm*ine* isoform compensates osmotic load in the hindgut and Malpighian tubules via an osmolyte carrier (Huang *et al*., 2002). Substantial progress in characterization of *ine* has been made by the heterologous expression of an ine-orthologous transporter from *M. sexta* in *Xenopus* oocytes (Chiu *et al*., 2000). That study revealed that *ine* responds to hyper-osmotic stimuli via the inositol triphosphate-coupled release of intracellular Ca^{2+}, which subsequently activates Ca^{2+}-dependent K^+ channels. The phylogenetic analysis indicates a single *ine* gene in *An. gambiae* and two splicoforms of a single *ine* gene in *D. melanogaster* (CG15444, located on the L2 chromosome). The insect *ine* group, with undefined ligand and transient functions, represents an evolutionary root of the NTTs and apparently provides primordial genetic sources in the differentiation of GLYT and GAT and monoamine neurotransmitter transporters. Therefore, the reasons why substrates for these putative transporters have remained elusive may not only be technical, but biological as well. The primary function of some of these proteins may be to regulate transmembrane ion fluxes in different tissues including the CNS.

Another orphan gene, named by similarity with a mammalian orphan group, has been extensively analyzed in *Drosophila* (Johnson *et al*., 1999). This gene, named bloated tubules (*blot*), exhibits complex and dynamic expression patterns during embryogenesis and supports processes that are essential for cell division, differentiation, and epithelial morphogenesis. Insect *ine* and *blot* do not cluster in high-resolution phylogenetic analyses. Nevertheless, their broader phylogenetic proximity with other uncharacterized “orphan type” sequences, as well as the related nutrient-type transporters, msKAAT1 and ms CAATCH1, from *M. sexta* and aeAAT1 and agAAT8 from mosquito (**Figures 6 and 10**; Section 5.9.8.5.2) indicates that several discrete functional groups may eventually emerge from under the “orphan” umbrella. The analysis showed five putative orphan genes in *An. gambiae* and four genes encoding seven presently known isoforms in *D. melanogaster*, which are in phylogenetic proximity with *blot* and represent a transition between the SNF

(Na^+/Cl^--dependent transporter) and PAT (proton amino acid transporter) families (Figure 6).

5.9.3.5. Choline Transporters (CHTs)

Acetylcholine (ACh) is the principal excitatory neurotransmitter in the insect CNS, although it has not been shown to have any role in transmission at the insect neuromuscular junction (Callec, 1985). ACh released from neurons activates postsynaptic receptors of both the ionotropic and metabotropic type and is then eliminated exclusively by enzymatic and nonenzymatic degradation, rather than a reuptake mechanism, as with other transmitters. Extracellular cholinesterases, widely exploited as insecticide targets, catalyze hydrolysis of ACh to choline and acetate; then specific transport systems remove the choline from the synaptic cleft via neuronal high-affinity, Na^+-driven reuptake. The resulting neuronal choline uptake represents a rate-limiting initial step in the ACh synthesis pathway in insects (Breer and Knipper, 1990).

An insect choline transporter (CHT) was isolated first from locust synaptosomes, using monoclonal antibodies that specifically blocked choline uptake *in vivo* (Knipper *et al*., 1989). The transporter was shown to be sensitive to the choline uptake inhibitor hemicholinium-3 and was localized by immunohistochemistry in ganglionic neuropils in the locust CNS. Initial attempts to identify CHT cDNAs in mammals using homology-based PCR were unsuccessful until 2000 when a first draft of the *C. elegans* genomic project became available. Using this information Okuda and colleagues cloned a nematode CHT (cho-1) and almost immediately thereafter the high-affinity hemicholinium-3 sensitive rat CHT1 (Okuda and Haga, 2000). All currently known CHTs are characterized by a 13-transmembrane domain configuration and are members of the sodium ion-dependent glucose transporter family, which corresponds to mammalian SLC5, with a SLC5A7 membership tag assigned to CHTs. This group includes transporters for diverse substrates, including glucose and galactose (urea and water), I^- (ClO_4^-, SCN^-, NO_3^-, Br^-), biotin, lipoate and pantothenate, as well as choline. In addition, SLC5 members may act as glucose *myo*-inositol (glucose) Na^+ (H^+) channels. This family of transporters is present in species from cyanobacteria to humans. They are placed in the Solute:Sodium Symporter (SSS) family (Saier, 2000b; TC 2.A.21), which comprises one of the largest groups of solute carriers in mammals (SLC5; Table 2). A putative insect CHT recently cloned from the cabbage looper (NCBI; trnCHT: AY629593; see Table 1) shows

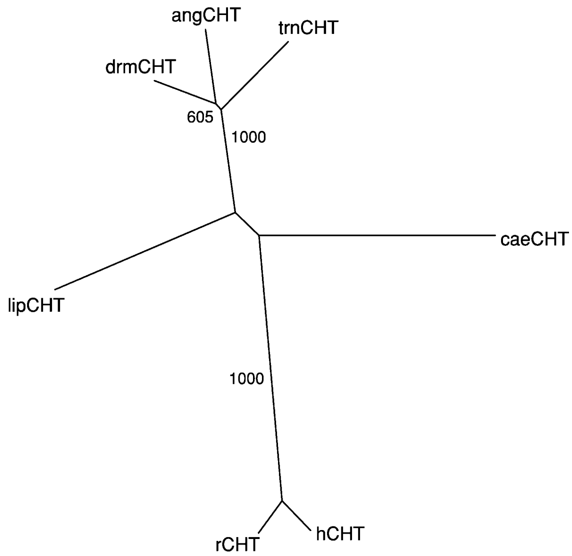

Figure 5 Dendrogram/bootstrap analysis of the amino acid sequences of insect choline transporters. Putative insect CHT sequences are included in the analysis, resulting in a discrete clade separate from the other invertebrate CHTs. The comparison was performed as in Figure 3, using amino acid sequences trimmed to the first and last predicted transmembrane domains. Accession numbers for the sequences are: human (hCHT; NP_068587), rat (rCHT; NP_445973), horseshoe crab (lipCHT; AAG41055), nematode (caeCHT; NP_502539), fruit fly (drmCHT; NP_650743), mosquito (angCHT; EAA07459), and cabbage looper (trnCHT; AY629593).

strong similarity to the known CHTs, and forms an orthologous cluster with putative CHT sequences from the fruit fly and mosquito genomes (Figure 5). The pharmacological effects of blocking choline uptake by this CHT may be different from blocking other neurotransmitter transporters since ACh synthesis should be suppressed without transmitter concentration building up in the synaptic space. It remains to be seen whether CHT may serve as a useful target for insecticide activity.

5.9.3.6. Vesicular Membrane Transporters

Neurotransmitters are taken up from the synaptic cleft by plasma membrane transporters and are sequestered in synaptic vesicles, thereby protecting the cell from potential toxicity and protecting the transmitters from intraneuronal metabolism (Masson *et al*., 1999). Low-affinity transporters, which are located in the vesicular membrane, transfer the transmitters into the vesicle lumen. Accumulation of transmitter in vesicles also facilitates uptake of transmitter into the cell by plasma membrane transporters, since it lowers the concentration gradient across the neuronal membrane. Vesicular transport can employ H^+ and ligand-specific electrochemical

motive forces that are induced by the activity of H^+ V-ATPases located on the vesicular membrane. Typically, such transporters exchange one or more protons inside the vesicle with a neurotransmitter molecule in the cytoplasm. There is less molecular information on these transporters than on their plasma membrane counterparts; however, it has become clear from sequence comparisons that the vesicular transporters characterized to date fall into three separate families; these are discussed immediately below.

5.9.3.6.1. Vesicular inhibitory amino acid transporters (vIAATs or vGATs) A vesicular GABA transporter was initially identified in *C. elegans* as a product of the *unc*-47 gene that mimics a GABA-defective behavior phenotype (McIntire *et al.*, 1993). This gene encodes a 10-TMD protein that colocalizes with synaptic vesicles of GABAergic neuronal terminals, where it mediates low-affinity vesicular accumulation of inhibitory neurotransmitters via an H^+/GABA(Gly) antiporter mechanism ($K_m^{GABA(Gly)} = 5(25)$ mM; McIntire *et al.*, 1997). Subsequently, when mammalian orthologs were cloned it was recognized that glycine may also be a physiological substrate, leading to the term vesicular inhibitory amino acid transporter (vIAAT, more commonly vGAT). These transporters are distantly related to other transporters that resemble SLC36 and SLC38 in mammals and bear some resemblance to a group of permeases that place them in the Amino Acid/Auxin Permease (AAAP) family of transporters (TC 2.A.18) in the TC classification scheme (Saier, 2000b; see also phylogenetic analysis in Section 5.9.8.1). Functional characterization of rodent orthologous transporters revealed that they contribute to GABA- and glycine-ergic signaling and glycine-dependent vesicular accumulation of GABA (Sagne *et al.*, 1997). However, no insect vIAAT has been characterized as yet.

5.9.3.6.2. Vesicular monoamine and acetylcholine transporters (vMATs and vAChTs) The first recognized and most thoroughly studied vesicular transporters make up the Vesicular Neurotransmitter Transporter (VNT) family (TC 2.A.1.22), a group classified within the Major Facilitator superfamily (Saier, 2000b). They include the vesicular transporters for monoamines (vMATs) and for acetylcholine (vAChT). These proteins have 12 predicted TMDs, which differ from the vIAATs (above) whose sequences predict only 10 (Masson *et al.*, 1999). Many vMATs and vAChT related transporters have been cloned from a variety of organisms, but the only insect vesicular transporter that has been studied to date is the *D. melanogaster* vAChT (Kitamoto *et al.*, 1998; Kitamoto *et al.*, 2000a; Yasuyama *et al.*, 2002). Additional data and analysis of phylogenetic proximity of dipteran vMATs to *H. sapiens* vMATs are included in Sections 5.9.5 and 5.9.9.1. Like the gene for nematode and vertebrate transporters, the gene for the fruit fly vAChT nests completely within the first intron of the choline acetyl transferase gene, encoding the enzyme that synthesizes ACh (Kitamoto *et al.*, 1998). Mutation analysis of the fly vAChT gene demonstrated that the function of the transporter is essential for viability, because mutants are recessive lethal (Kitamoto *et al.*, 2000b). VAChT is involved in cholinergic transmission since decreased activity in heterozygous mutants resulted in defects in the giant fiber pathway, a neural circuit known to contain cholinergic synapses. Functional studies of the fruit fly vAChT in an isolated cell system should yield information on its kinetics.

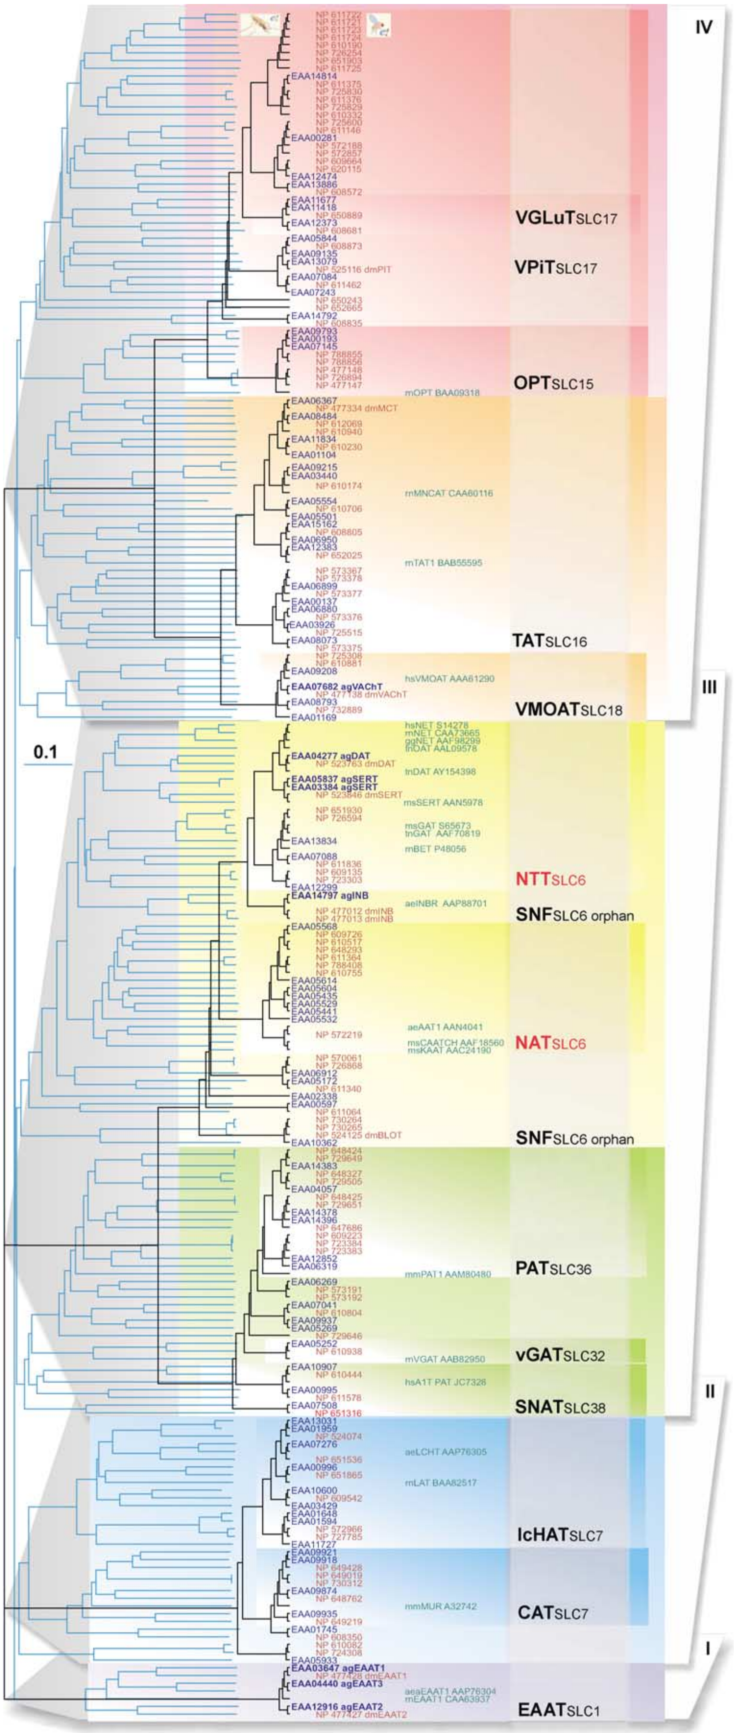
5.9.3.6.3. Vesicular glutamate transporters (vGLUTs) Vesicular transporters for glutamate were only recently recognized when a human brain-specific inorganic phosphate transporter (BNPI) was found to also transport glutamate (Bellocchio *et al.*, 2000). Three subtypes of mammalian vesicular glutamate transporter are now known (SLC17; see Section 5.9.9.4), but no insect examples have yet been studied. Based upon their structure, these transporters also belong to the Major Facilitator superfamily (see above), but within a different family, the Anion:Cation Symporter (ACS) family (TC 2.A1.14; **Table 1**).

5.9.4. Nutrient Amino Acid Transport in Insects

5.9.4.1. Early Studies of Insect Amino Acid Uptake

Clements (1992) reviewed the work on amino acid uptake in Malpighian tubules of living insects by Wigglesworth, Ramsay, Phillips, and others. Giordana *et al.* (1989), Castagna *et al.* (1997), and Wolfersberger (2000) reviewed the physiology and biochemistry of amino acid uptake in isolated midguts. In the early 1970s, Signe Nedergaard (1972) reported the transport of alpha-aminoisobutyric acid from lumen to blood-side of the isolated caterpillar midgut by a voltage-dependent process that requires oxygen and K^+ but is independent of active K^+ transport. Studying brush border membrane vesicles from caterpillar midgut, Hanozet, Giordana, and Sacchi (Hanozet *et al.*, 1980) showed

that phenylalanine is cotransported with K^+ by a voltage-dependent process. Since the K^+ pump is electrogenic (Harvey *et al.*, 1968) and oxygen dependent (Harvey *et al.*, 1967), it appeared that it uses energy from ATP hydrolysis to charge the apical plasma membrane (lumen positive to cell) and that the voltage drives a positively charged K^+ amino acid complex across the membrane, carrying both solutes into the cell. The oxygen dependence arises because the midgut has little anaerobic reserve, ATP levels dropping as oxygen pressure drops (Mandel *et al.*, 1980). After the K^+ pump-containing, goblet cell apical membrane was isolated (Cioffi and Wolfersberger, 1983; Harvey *et al.*, 1983), the K^+ pump was shown to consist of an H^+ translocating ATPase (Wieczorek *et al.*, 1989) that charges the membrane and is thought to drive secondary K^+/$2H^+$ exchange (Wieczorek *et al.*, 1991). The membrane charging by the V-ATPase has been confirmed many times (Wieczorek *et al.*, 1999b) but the nature of the secondary K^+/H^+ exchange remains unresolved. The working hypothesis for amino acid uptake is that the H^+ V-ATPase charges the apical membrane (lumen positive to cell) and that the voltage drives amino acid:K^+ cotransport from lumen to cell.



5.9.4.2. Amino Acid Uptake by Brush Border Membrane Vesicles

Several major amino acid transport systems have been characterized in brush border membrane vesicles (BBMV) from lepidopteran midgut. Uptake has been studied in *Philosamia cynthia* (Giordana and Parenti, 1994), *M. sexta* (Hennigan *et al.*, 1993a, 1993b; Reuveni and Dunn, 1994; Bader *et al.*, 1995; Liu and Harvey, 1996a, 1996b), *Bombyx mori* (Parenti *et al.*, 2000; Leonardi *et al.*, 2001a, 2001b) and *Pieris brassicae* (Reuveni and Dunn, 1994; Giordana *et al.*, 1989; Wolfersberger, 2000). Facilitative transport systems are widespread (Wolfersberger, 2000) along with separate K^+- or Na^+-dependent neutral and cationic amino acid transporters, which are driven mainly by the membrane potential (Giordana and Parenti, 1994; Castagna *et al.*, 1997). Some evidence suggests that leucine uptake is partially modulated by a hormonal and nutrient-related mechanism (Leonardi *et al.*, 2001b). Nutrient glutamate transport appears to be anomalous (Xie *et al.*, 1994). In summary, four principal transport systems were characterized: (1) a broad spectrum neutral amino acid:K^+ cotransport system; (2) an arginine K^+ cotransport system; (3) an acidic amino acid system with anomalous properties; and (4) a glycine or proline transporter. Extensive kinetics studies on BBMV showed that the transport systems had low affinity for amino acids (K_m around 1 mM) and K^+ (K_m around 30 mM). Presteady state kinetic studies on BBMV suggested a symmetric on/off mechanism (Parenti *et al.*, 1992). The kinetic studies also suggested that there might be more than one transporter for each amino acid and that several amino acids use the same transporter. Hence, the kinetic parameters from BBMV studies represent average values rather than values from single transporters.

Surprisingly, there are no available references on amino acid uptake by isolated brush border membrane vesicles from larval midgut of mosquitoes. There is a single report of uptake of radiolabeled amino acids in intact midgut of adult *Anopheles stephensi* (Schneider *et al.*, 1986). There is a published method for vesicle preparation from midgut preparations, but it was used only for *Bacillus sphaericus* binding studies (Nielsen-LeRoux and Charles, 1992). Therefore, most existing insect vesicle transport data are from caterpillars, taking advantage of their large size in preparation of large tissue samples. Nevertheless, dipteran larvae of *An. gambiae* and *D. melanogaster* serve in the postgenomic era as more convenient and comprehensive models for molecular, cellular, and integrative studies of transport biology, including explorations of amino acid transport metabolons. BBMV studies on caterpillars confirmed voltage-driven, amino acid transport.

5.9.5. Postgenomic Analysis of Insect AATs

In the postgenomic era, there is a rapid advance toward the identification of virtually all transport proteins in a growing number of genomic models. This advance facilitates the accumulation and systematization of molecular and physiological data, which makes it possible to deduce the function of particular transporters by their phylogenetic proximity, which in turn enables one to identify new species and groups of transporters with previously unknown functions. This review takes advantage of this new opportunity. A matrix of dipteran transporters, together with reference sequences of characterized amino acid transporters, was used to establish phylogenetic reciprocity within comprehensive genomic populations of insect amino acid transporters. The resulting phylogram (**Figure 6**) incorporates the best reciprocal matches from predicted gene products of *D. melanogaster* (Adams *et al.*, 2000) and *An. gambiae* (Holt *et al.*, 2002), along with characterized metazoan amino acid transporters, which are deposited in the National Center for Bioinformatics (NCBI) databases. The properties of insect amino acid transporters will be discussed in the framework of the classical divisions

of neurotransmitter phenotypes and a novel division of nutrient amino acid phenotypes. Then this description is integrated into a new scheme that discloses phylogenetic relationships of such transporters in the order in which they are self-clustered in the low-resolution, unrooted phylogram (Figure 6), which was constructed by using ClustalX software for progressive multiple sequence alignment and comparison (Thompson *et al*., 1997). Since there are an indefinite number of phenotypic transitions and putative substrates within several phylogenetic groups, an entire group of amino acid transporters was included if at least one of its members, or its reciprocal sequence homolog, serves as a carrier of amino acids or related substrates. The final phylogenetic tree (Figure 6) is a product of multiple iterations of comprehensive subsets of sequences. It includes 85 gene products of *An. gambiae* (blue font color, proximal column) and 108 gene products of *D. melanogaster*, which are encoded by 88 genes, but some are represented by several established splicoforms (red font color, middle column). Included also are 25 transporters, which were cloned and characterized from other insect species (green font color, distal column). Several *An. gambiae* gene products, which are definitely orthologs of cloned and characterized transporters, are indicated in bold. Six families that differ substantially in their electrochemical transport mechanisms are represented by different background colors. In addition to the integrated low-resolution tree in Figure 6, analyses of phylogenetic proximity of mammalian and dipteran transporters for each particular family are included, which are shown here as ClustalX dendrograms, phylograms, and/or cladograms, depending upon the view that is best suited for representing peculiarities within a particular group. Due to the lack of clear consensus in transport protein classification, we will follow the most natural solute carrier nomenclature (SLC), which rests on a comprehensive subset of characterized *H. sapiens* and other mammalian transporters. Four large clusters that exhibit phylogenetic proximity between different families of insect amino acid transporters are introduced in Figure 6 as panels with a Roman integer.

Special emphasis is placed on the insect Nutrient Amino Acid Transporter (NAT) subfamily which is introduced here for the first time. It resides within the SNF, and apparently represents a group of lineage-specific, essential nutrient amino acid transporters, which appear to be good targets for insect population control (see Section 5.9.4).

Figure 6 Comprehensive low-resolution phylogram (blue tree) and cladogram (black tree) of dipteran amino acid transporters. The unrooted phylogenetic trees were constructed using Clustal X software (Thompson *et al*., 1997), which utilizes a neighbor-joining algorithm for tree reconstruction (Saitou and Nei, 1987), converted to Windows metafile by TreeView(Win32) (Page, 1996) and decorated with CorelDraw software. This phylogenetic analysis includes 193 dipteran sequences (Smith-Waterman all-against-all e-value cutoff $<10^{-5}$), which represent putative orthologs of 10 solute carrier families (SoLute Carrier numbers; SLC with Arabic integers) and 15 identified[1] phenotypes of amino acid transporters (large font on the transparent ribbon). Sequences are represented by nonredundant subsets of gene product accession numbers, which can be used to retrieve these sequences from NCBI protein databases (National Center for Biotechnology Information (***NCBI***)[2]). First row from the left (blue font) are 85 putative gene products identified in *An. gambiae*, each of which is represented by a single splicoform; second row (red font) 108 gene products found in *D. melanogaster*, which are encoded by 88 genes, but some are represented by several established splicoforms; third row (green font) represent 25 characterized transporters from various species that are used to reference tree clusters[3]. Common transporter phenotype abbreviations are used, e.g.: EAAT, excitatory amino acid transporter; CAT, cationic amino acid transporter; lcHAT, light chain subunit of heterodimeric amino acid transporter; SNAT, sodium neutral amino acid transporter; vGAT, vesicular GABA transporter; PAT, proton amino acid transporter; SNF, sodium neurotransmitter transporter family; NAT, nutrient amino acid transporter; NTT, neurotransmitter transporter; vMAT, vesicular monoamine transporter; TAT, T-system amino acid transporter; OPT, oligopeptide transporter; P_iT, inorganic phospate (P_i) transporter; vGluT, vesicular glutamate transporter. Sequences from different lineages are shown in different font color, e.g: *Ae. aegypti*, green; *An. gambiae*, blue; *D. melanogaster*, red; *H. sapiens*, black. Accession numbers from first draft of *An. gambiae* genome annotation (EAA numbers) are duplicated by accession numbers for recently reviewed sequences (XP_#). Tree reconstruction was done from the unaltered alignment of sequences as they were deposited in the NCBI database, so be aware that some *An. gambiae* sequences may have incorrect composition of open reading frame as well as prediction of 3′ and 5′ ends, which could produce tree distortion. Scale bar are evolutionary distances in mutations per site. [All families in **Figure 6** are shown in amplified form in appropriate sections of this chapter.]

[1]Not all transport phenotypes are shown in this phylogram; see other figures for details.

[2]Low dash, which links NP and numerical integers, are missing due to file conversion and must be inserted to avoid accession errors, e.g. NP 477427 represents NP_477427. Accession numbers starting with EAA integer are from first draft of *An. gambiae* genome annotation; since a few of them will disappear during future revisions of genomic databases they are duplicated by new accession numbers started with XP_ in the high resolution phylogram (Figures 8–10 and 13–17).

[3]Each referencing sequence is represented by a transporter phenotype name following by an accession number, e.g., msCAATCH AAF18560 is *M. sexta* cation amino acid transporter channel; other species abbreviations here and on other figures are: ae, *Ae. aegypti*; dm, *D. melanogaster*; gg, *Gallus gallus*; hs, *Homo sapiens*; rn, *Rattus norvegicus*; mm, Mus musculus; tn, *Trichoplusia ni*.

5.9.6. AAT Cluster I (SLC1)

This type of transporter, abundant in metazoan lineages and present in bacteria and Archaea, is absent in plants and fungi (**Table 2**). Mammalian SLC1 transporters are extensively characterized, comprising two ASCT (alanine, serine, and cysteine transporters) and five EAAT genes in *Homo sapiens*. Phylogenetically, EAAT is a progeny of the ASCT group which together comprise only one SLC1 (solute carrier type 1) family in mammals. It is devoted to small nutrient and excitatory (glutamate and aspartate) amino acid transporters. Mammalian SLC1 genes encode two classically characterized carrier systems (**Table 2**). System ASC (ASCT1 and 2) serves as a facultative sodium ion driven substrate provider of glutamine, alanine, serine, cysteine, and asparagine in tissues with a low capacity or absence of anabolic pathways for the production of such amino acids (Arriza *et al.*, 1993; Utsunomiya-Tate *et al.*, 1996; Furuya and Watanabe, 2003; Wolfgang *et al.*, 2003) and in proliferating tissues, including tumors (Kekuda *et al.*, 1996; Li *et al.*, 2003). Intriguingly, some transporters of this group have been identified as retroviral receptors (Rasko *et al.*, 1999); for example, SLC5A1 (ASCT2) mammalian transporters are utilized as a surface binding receptor and an intracellular gateway by a diverse group of retroviruses (Marin *et al.*, 2003).

System $X^{A,G}$ (EAAT) maintains local glutamate/aspartate concentrations, including those in central excitatory insect synapses (Donly *et al.*, 2000), glial tissue (Kanai and Hediger, 1992; Kanai *et al.*, 1993; Kirschner *et al.*, 1994; Suchak *et al.*, 2003), visual and olfactory afferents (Arriza *et al.*, 1997; Besson *et al.*, 1999; Kucharski *et al.*, 2000), macrophages (Rimaniol *et al.*, 2000), and osteocytes (Huggett *et al.*, 2002). Mammalian EAAT genes appear to have diverged through adaptation for particular physiological conditions (Arriza *et al.*, 1994; Amara and Fontana, 2002) and specifically may expand their functions beyond the tuning of excitatory amino acids uptake at membranes that surround a synaptic cleft. For example, EAATs may serve as facultative providers of cysteine for glutathione synthesis (Chen and Swanson, 2003) or act as leak channels and/or ligand-gated chloride channels (Fairman *et al.*, 1995; Arriza *et al.*, 1997).

Apparently, the ASCT group is absent from dipteran genomes, which also appear to have few EAAT genes. EAAT comprises two established genes in *D. melanogaster* and three genes in *An. gambiae*, which split into two clusters in the dipterans (**Figure 6**), but have no obvious orthologs among the five mammalian transporters. A brief description of cloned EAATs from several insects is given above in Section 5.9.3.3.

5.9.7. AAT Cluster II (SLC7)

Like Cluster I, Cluster II corresponds to one solute carrier family in mammals (SLC7) that integrates two large functionally and structurally different groups of transporters, the cationic amino acid transporter (CAT) subfamily and the heterodimeric amino acid transporter (HAT) subfamily, based on phylogenetic, structural, and physiological properties (Verrey *et al.*, 2003). SLC7-related transporter heterogeneity has been partially explored in insects and one representative HAT-homologous sequence (AeaLAT) has recently been cloned from *Ae. aegypti* (Jin *et al.*, 2003). Phylogenetic analysis of insect transporters revealed three specific clusters. Two large and distal clusters apparently comprise insect versions of CAT and HAT subfamilies, respectively. The third small cluster is parental to the CAT/HAT cluster (**Figures 6** and **7**), which by its phylogenetic loci represents transporters similar to mammalian orphan SLC7A4, with an as yet indefinite function (Wolf *et al.*, 2002). In mammals SLC7 genes encode a broad variety of transport systems including sodium independent b^+, y^+, y^+L (for cationic AA) as well as $b^{0,+}$ and a sodium-dependent system $B^{0,+}$; y^+L (for neutral AAs) (Closs, 2002; Verrey *et al.*, 2003). Since very few insect transporters in this phylogenetic group are characterized, a brief description of characterized mammalian transporters is included below, along with a description of the phylogenetic pattern of related dipteran amino acid transporters (**Figure 7**).

5.9.7.1. Cationic Amino Acid Transporters (CATs)

The cationic amino acid transporter (CAT, SLC7A1–4) subfamily comprises 14 TMD transporters that are typically located on the plasma membrane (Wolf *et al.*, 2002). Most of these transporters regulate local concentrations of cationic amino acids through (1) facilitated diffusion and/or (2) differential amino acid exchange between relatively saturated physiological domains in organisms, e.g., growing and/or actively metabolizing cells, as well as nutrient and secretory epithelia (Verrey *et al.*, 2003). The first CAT was identified as the receptor for murine ecotropic leukaemia viruses in the mouse, MuLVR or mmCAT1, which mimics a y^+-transport system (sodium ion-independent L-arginine, L-lysine, and L-ornithine uptake) phenotype in *Xenopus* oocytes (Albritton *et al.*, 1989; Kim

Notes, abbreviations, and special characters: + and −, positive and negative charges; AP[1], ancillary protein (4F2hc/CD98 or rBAT); AP[2], ancillary protein (CD147); U, uniporters (facilitated diffusion), E, exchanger (antiporters); S, symporters (cotransporter); C, channels (high throughput tunneling of inorganic ions); Sb, substrate; H, M, L, apparent substrate affinity high $<10^{-5}$, medium 10^{-3}–10^{-4}, and low $>10^{-3}$, respectively; lys, lysosomal membrane; ep, epithelial membrane; ves, vesicular membrane; na, not available.

Ligands: specific amino acid are shown according to a single capital letter nomenclature; HA, histamine; DA, dopamine; 5HT, serotonin; NE, norepinephrine (noradrenalin); EP, epinephrine (adrenaline); ACh, acetylcholine; Ch, choline; GABA, gamma amino butyric acid; SUSOI, prediction from available open reading frame sequences using SUSOI algorithm and remote server (http://sosui.proteome.Bio.tuat.ac.jp/sosui_subunit.html) Mitaku Group, Department of Biotechnology, Tokyo University of Agriculture and Technology.

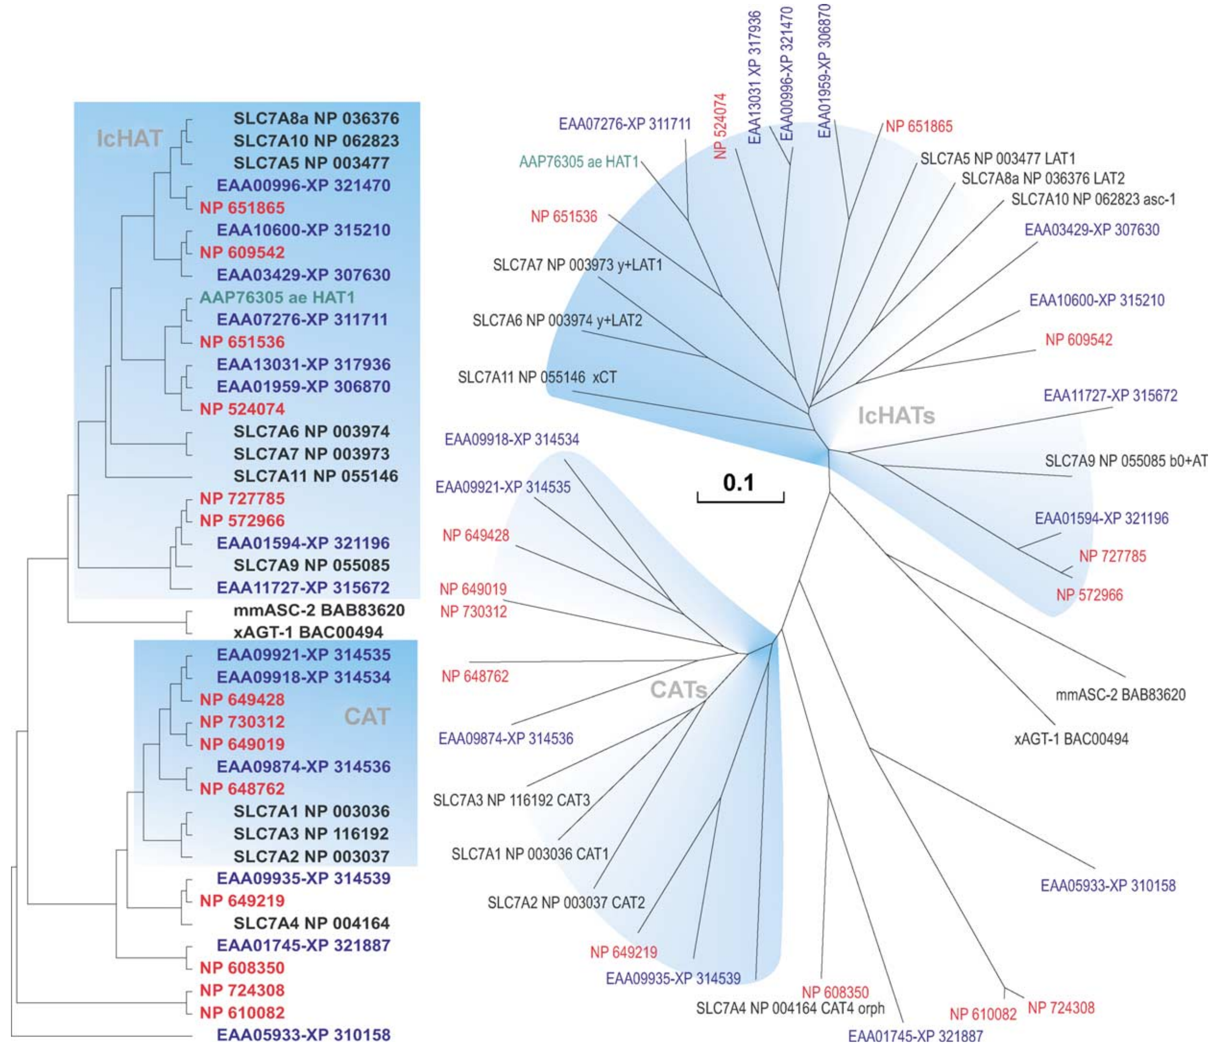

Figure 7 Phylogenetic proximity of dipteran and mammalian cationic amino acid transporter (CATs) and light chain subunits of heterodimeric amino acid transporter lcHATs (SLC7). Cladogram rooted with an EAA05933-XP_310158 *An. gambiae* sequence (left) and unrooted dendrogram (right) of putative dipteran CATs and lcHATs along with identified and partly characterized orthologs from *H. sapiens* genome.

et al., 1991). Now mammalian CAT subtypes 1–3 (SLC7A1–3, respectively) represent a large group of comparatively well-characterized Na^+-independent transporters. CATs in nonepithelial tissues predominantly function as y^+-system nutrient cationic amino acid providers. In epithelial tissues, CATs mediate basolateral transport which apparently is an essential component of transepithelial transport of amino acids. Thermodynamically, CAT types 2 and 3 mediate downhill diffusion (uniport) of selected cationic amino acids with extremely weak coupling or no coupling to other substrates. Since its substrates carry charge at physiological pH, CAT transport can be electrophoretic as well. In contrast, CAT type 1 is strongly trans-stimulated by intracellular substrates and may act as a thermodynamically coupled exchanger of specific intracellular and extracellular amino acids. Neutral amino acids can be recognized by most CATs with rather low apparent affinity (Closs, 2002). In mammals, CAT subtypes exhibit abundant but subtype-specific spatial expression and immunolabeling patterns and appear to be genetic factors of several metabolic and immune diseases, including cystinuria and lysinuric protein intolerance (Simell, 2001). In addition to their relatively universal function in absorption and emission of cationic amino acids including arginine, CATs serve as rate-limiting substrate providers for enzymatic production of nitric oxide (NO) in endothelial cells and macrophages. CATs undergo complex regulation at transcriptional (Fernandez *et al*., 2002) and posttranscriptional (Graf *et al*.,

2001) levels, which include modulation by substrates and nontransported ligands, as well as by cytoskeleton proteins (Zharikov *et al.*, 2001).

5.9.7.2. Heterodimeric Amino Acid Transporters (HATs)

The heterodimeric amino acid transporter (HAT, mammalian SLC7A5–11) subfamily comprises 12-TMD transport proteins (also referred to as light chain catalytic subunit, ~40 kDa) whose functional expression requires association with its ancillary counterpart peptide, a heavy chain (~80 kDa) subunit (Verrey *et al.*, 2003). The heavy chain subunits (mammalian SLC3) are currently represented by two proteins with apparent α-glucosidase homology: 4F2hc, the heavy chain of the lymphocyte activation antigen 4F2 (Hemler and Strominger, 1982) and rBAT, a type II membrane glycoprotein related to the $b^{0,+}$ amino acid transport phenotype (Bertran *et al.*, 1992; Tate *et al.*, 1992; Wells and Hediger, 1992). Heavy chain proteins have a single membrane spanning domain and an extracellular globular C-terminal domain in their secondary structure. Their interaction with light chain subunits is stabilized via 4F2hc-specific disulfide covalent binding (Chillaron *et al.*, 2001) or rBAT-specific noncovalent interaction (Pfeiffer *et al.*, 1998). The suggested role of the heavy chain SLC3 component is in coordinated delivery of the heterodimeric complex to the plasma membrane whereas the light chain SLC7 of HATs serves as a carrier mechanism (Palacin and Kanai, 2003; Verrey *et al.*, 2003).

In contrast to facilitators and nonobligatory exchangers like CATs, the obligatory exchangers, HATs, are associated with a great variety of transport systems that are diverse in terms of distribution and substrate selectivity, including L system for large neutral amino acids; asc system for small neutral amino acids, e.g., Ala, Ser, Cys; x_c^- system for anionic amino acids; and $y^+L/b^{0,+}$ system that combines carriers for cationic and neutral amino acids (Verrey *et al.*, 2003). Virtually all cloned HATs are obligatory exchangers of amino acids, except for the sodium ion driven y^+L transport of neutral amino acids by SLC7A6 or SLC7A7 and SLC3A3 HATs (Pfeiffer *et al.*, 1999; Broer *et al.*, 2000). The varied physiological roles of HATs have been extrapolated from their activity in heterologous expression systems, distribution, and earlier brush border vesicle analyses. For example, in nutritive epithelial tissues they serve as basolateral complements of apical B^0 and $b^{0,+}$ transporters, which are both essential for transepithelial absorption of amino acids (Fernandez *et al.*, 2003). They also may serve as tertiary active transport mechanisms for epithelial reabsorption of cysteine and dibasic amino acids (Chillaron *et al.*, 1996). In nonpolarized cells, heterodimeric transporters serve in several unique mechanisms in which nutrient neutral amino acid uptake is thermodynamically coupled to emission of metabolized or redundant intracellular neutral amino acids (Meier *et al.*, 2002). Notable examples of HAT function are neuronal and glial activity of a SLC7A11/xCT transporter, which is heterologously associated with a 4F2hc subunit (Sato *et al.*, 1999) and mediates 1 : 1 exchange of extracellular cysteine for intracellular glutamate. This transporter, therefore, represents a rate-limiting component in GSH (glutathione) synthesis pathways. GSH is a tripeptide of glycine, glutamate, and cysteine that is crucial for cells and tissues that tolerate endogenous free-radical stress, e.g., activated macrophages, hypothalamic neurons, a variety of glial cells and pancreas, as well as several cell culture lines (Bassi *et al.*, 2001; Bridges *et al.*, 2001; Sato *et al.*, 2002; Tomi *et al.*, 2003; Wang *et al.*, 2003).

5.9.7.2.1. SLC7 related genes in dipteran models Transporters structurally similar to SLC7 have been reported throughout all life kingdoms; however, these have quite specific patterns of taxonomic proximity for particular species (**Table 2**). The insect CAT cluster, defined by phylogenetic reciprocity to mammalian CATs, includes six genes in both dipteran models (**Figures 4** and **7**). However, insect CAT genes do not form exact orthological matches with mammalian CATs, except for the SLC7A4 (NP_004164) gene, which clusters with insect NP_649219 and EAA09935 sequences (**Figure 7**). In contrast, insect CATs exhibit better interspecific homology by forming four orthologous clusters when they are analyzed within frames of dipteran lineages (**Figure 6**). It is most likely that proximal insect CATs are functional equivalents of mammalian CATs 1–3, which evolved via lineage-specific gene duplications; however, exact functions remain elusive, pending cloning and functional characterization of such gene transcripts. In addition to the four CATs characterized in mammalian models, both *Anopheles* and *Drosophila* genomes include two more, apparently parental, genes that are at a lower phylogenetic level relative to CATs and HATs.

Insect HATs comprise nine putative genes in *An. gambiae* but only five genes in *D. melanogaster*, which together occupy five apparently orthologous clusters (**Figures 6** and **7**). Only one such group forms a cluster with mammalian SLC7A9 (NP_055085) transporters (**Figure 7**). Several *An. gambiae* genes are not mapped, so the question

about the exact number of HAT genes in this model remains to be clarified. One HAT gene cloned and characterized from *Ae. aegypti* (Jin *et al.*, 2003), AAP76305, appears to be orthologous to EAA07276 and NP_651536 genes in *An. gambiae* and *D. melanogaster*, respectively (see Section 5.9.7.2.3).

5.9.7.2.2. SLC3-related genes in dipteran models SLC3 proteins (heavy chain subunit of HAT; **Figure 8**) serve as obligatory cofactors of SLC7 transport proteins, but do not appear to be phylogenetically related to some membrane solute carrier family. In contrast, this subunit is homologous to the α-amylase or glycosyl hydrolase Family 13, all of which bear a unique catalytic $(\beta/\alpha)_8$-barrel domain with the active site being at the C-terminal end of the barrel beta-strands. These proteins share a functional signature in that they catalyze a variety of glycoside bond cleavage/formation reactions (MacGregor *et al.*, 2001). The extracellular domain of SLC3 members has up to 30% to 40% peptide identity with insect maltases and bacterial α-glucosidases (Palacin and Kanai, 2003), which in turn indicates a possible route of evolution common for α-amylase family proteins (Janecek, 1994). Nevertheless, rBAT (see below) lacks amylase-specific activity when heterologously expressed in *Xenopus* oocytes (Wells and Hediger, 1992); it appears to lack amylase-specific catalytic residues (Chillaron *et al.*, 2001) when compared to *Bacillus cereus* oligo 1,6-glucosidase (O1,6G), which is available in the Protein Data Bank (PDB) (Watanabe *et al.*, 1997).

At present, two members of mammalian SLC3 that form functional HATs are characterized (Palacin and Kanai, 2003): rBAT (SLC3A1) was initially identified by expression cloning in *Xenopus* oocytes (Bertran *et al.*, 1992; Tate *et al.*, 1992; Wells and Hediger, 1992); and 4F2hc (SLC3A2), was initially identified as a lymphocyte activation antigen (Hemler and Strominger, 1982). Both of these proteins appear to be widespread throughout the Metazoa. They also share remarkable homology with a number of putative genes from bacteria and fungi. However, the affiliation of these bacterial and fungal proteins with HAT forming proteins requires a detailed comparison of sequences and secondary

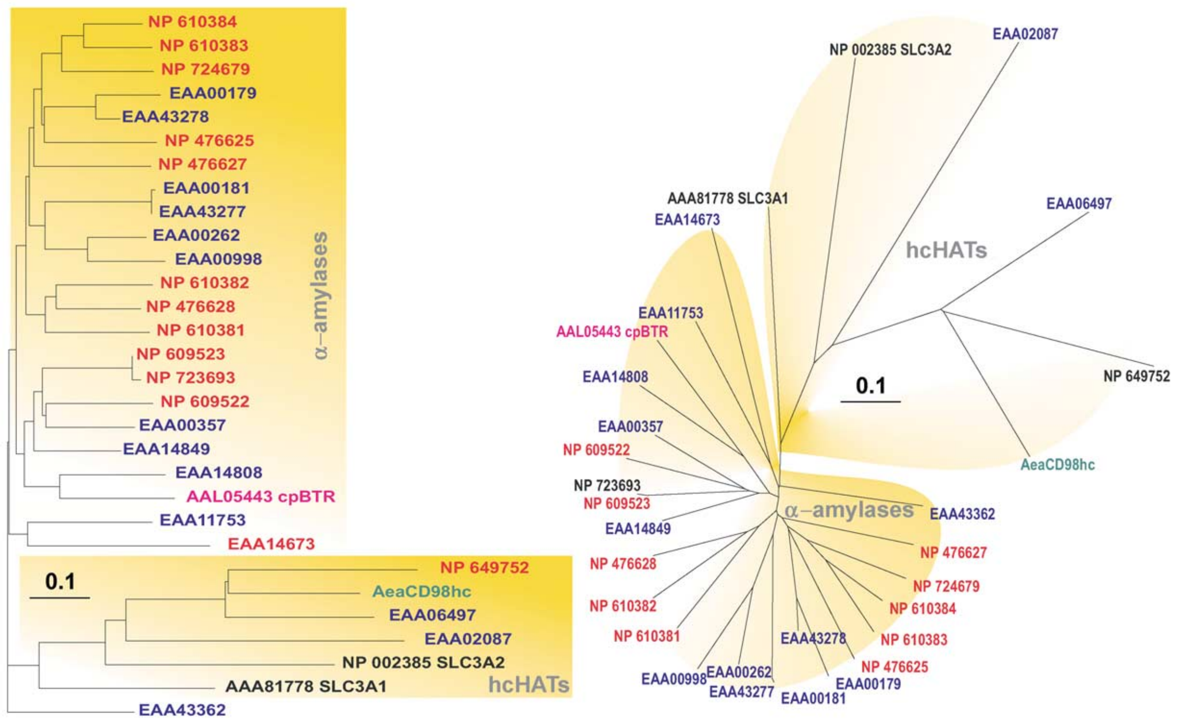

Figure 8 Phylogenetic proximity of mammalian HATs (hcHATs, SLC3) with dipteran orthologs of heavy chain subunits and with amylases. Unrooted phylogram (left) and dendrogram (right) of putative heavy chain subunit of HATs and amylases from dipteran genomes, along with known orthologs from *H. sapiens* genome (black font). Other font colors: green, heavy chain subunit of heterodimeric amino acid transporter from *Ae. aegypti*; blue, *An. gambiae* sequences; red, *D. melanogaster* sequences; pink, a binary toxin-binding alpha-glucosidase from *Culex pipiens*. Scale bar is evolutionary distances in mutations per site.

structures as well as functional assay, because of their apparent orthology with amylases. Intriguingly, SLC7 homologous proteins are present in plants and Archaea that lack SLC3 counterparts. This fact makes dialectic the obligatory requirement of SLC3 and CLC7 association at least in some lineages.

Two putative genes resembling the mammalian SLC3A2 heavy chain subunit are currently found in the *An. gambiae* genome (EAA06497, located on the X chromosome; and EAA02087, not yet mapped) whereas only one gene is present in *D. melanogaster* (NP_649753, located on the 3R chromosome). All other dipteran sequences with apparent SLC3 homology reside in an α-amylase specific gene cluster (**Figure 8**). Intriguingly, some products of these genes are recognized as toxin receptors, e.g., AAL05443, which encodes the receptor of the *B. sphaericus* binary toxin (BT) in *Culex pipiens* midgut (Darboux *et al.*, 2001). Another important finding from analysis of dipteran sequences is that heavy chain proteins apparently evolved not from α-amylases but from some common primordial ancestor (**Figure 6**).

5.9.7.2.3. Cloned insect HATs from *Ae. aegypti*; (AeaLAT + AeaCD98hc) Two complementary subunits (AeaLAT and AeaCD98hc, light chain and heavy chain subunits, respectively) of an insect HAT have been cloned recently from the mosquito *Ae. aegypti*. Like mammalian HATs, insect transporters require expression of complementary subunits to produce a functional L-amino acid transporter phenotype in *Xenopus* oocytes. Heterologously expressed mosquito AeaLAT+AeaCD98hc subunits mediate uptake of large neutral and basic amino acids, partly resembling y^+L system transporters. Small acidic and neutral amino acids appear to be poor substrates for this transporter (Jin *et al.*, 2003). Like mammalian HAT, these insect transporters can utilize a Na^+ gradient (upregulated ~44%) for the uptake of neutral amino acids (L-leucine; $K_m^{leu} = 67\,\mu M$), but not basic amino acids (L-lysine), which is virtually Na^+-independent at pH of 7.4 (Jin *et al.*, 2003). It has been suggested that the electrochemical gradient for amino acids at high extracellular concentrations appears to be the major factor that enables amino acid transport by AeaLAT+AeaCD98hc. AeaLAT showed high-level expression in the gastric caeca, Malpighian tubules, and hindgut of larvae. In caeca and hindgut, expression was in the apical cell membrane. However, in Malpighian tubules and midgut (which showed low-level expression), the transporter was detected in the basolateral membrane. This expression profile supports the conclusion that this AeaLAT + AeaCD98hc pair mediates a nutrient amino acid emission from posterior midgut epithelial cells to hemolymph (Jin *et al.*, 2003). A combination of similar basal y^+L HATs with apical $B^{0,+}$ transporters, such as msKAAT1, msCAATCH1, and (recently cloned from mosquito larvae midguts) aeAAT1 and agAAT8 may comprise a complete transepithelial transport metabolon for nutrient amino acid uptake. It has been stated that the apical location of AeaLAT in the gastric caeca implies its involvement in the absorption of amino acids from the lumen (Jin *et al.*, 2003). Similarly, its basal location in the midgut suggests that it may participate in the emission of amino acids or their derivatives to the hemolymph for circulation to the gastric caeca and cardia lumen where they are required for assembly of the peritrophic matrix.

5.9.8. AAT Cluster III (SLC6, SLC32, SLC36, SLC38)

5.9.8.1. SNATs and PATs (SLC38, SLC32, SLC36)

Sodium neutral amino acid transporters (SNATs), vesicular GABA Transporters (vGATs), and proton amino acid transporters (PATs), SLC38, SLC32, and SLC36, respectively, are grouped together because they represent phylogenetically related groups of transport proteins with a consecutive phylogenetic hierarchy as well as common motifs in their secondary structure, such as the presence of 10–12 TMDs. This clustering of insect transporters also corresponds to a previously identified, eukaryotic-specific, amino acid/auxin permease superfamily (Young *et al.*, 1999). Although the homology of these superfamilies of metazoan transporters is certain, to judge the exact orthology of particular insect transporters with known mammalian SNATs and PATs is problematic, because of extensive lineage-specific gene duplication/loss and lack of characterized insect transporters related to this superfamily.

5.9.8.2. Sodium Neutral Amino Acid Transporters, SNATs (SLC38)

This cluster represents the parental group in the SNAT + PAT superfamily, whose members fall into several consecutive phylogenetic levels in dipteran models (**Figures 6 and 9**). In mammals, characterized SNATs comprise System A and N transporters, each of which mediates a low-affinity transport ($0.3 < K_m^{substrate} < 2\,mM$) of varied subsets of small,

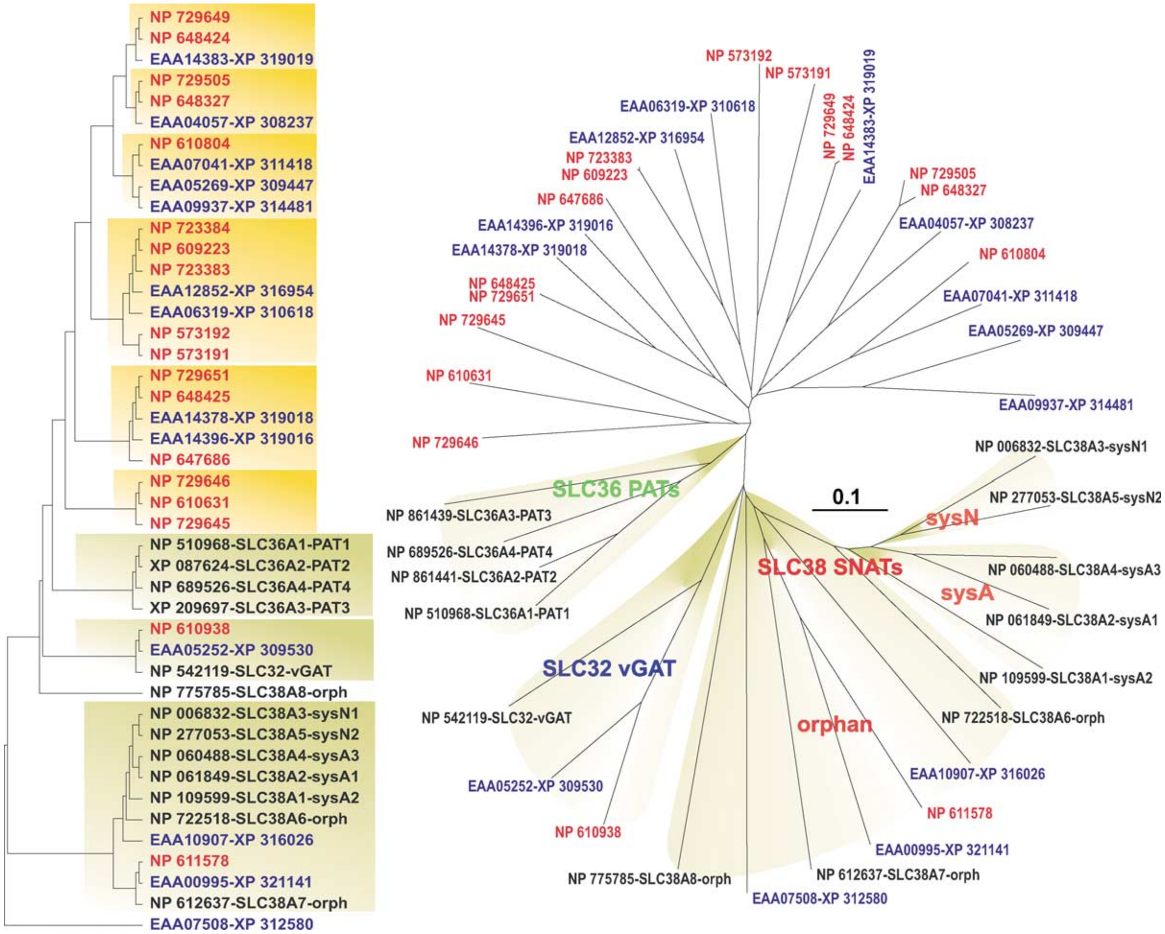

Figure 9 Phylogenetic transitions between dipteran and mammalian sodium neutral amino acid transporters (SNATs, SLC38), proton amino acid transporters (PATs, SLC36) and vesicular GABA transporter (vGAT, SLC32). Unrooted phylogram (left) and dendrogram (right). Font colors: blue, *An. gambiae* sequences; red, *D. melanogaster* sequences; black, *H. sapiens* sequences. Other abbreviations: sysA and sysN, systems A and system N transporters, respectively. Scale bar is evolutionary distances in mutations per site.

aliphatic amino acids (Mackenzie and Erickson, 2003). System A transporters appear to be broadly expressed in all mammalian tissues and to mediate Na^+-driven, electrophoretic, and pH sensitive neutral amino acid uptake through plasma membranes. In contrast, system N transporters have narrower substrate profiles and utilize proton motive forces, which may facilitate a reverse amino acid transport and consequently an active emission of catabolic amino acids (Chaudhry *et al*., 2001; Broer *et al*., 2002). Both systems are known to be tightly regulated via hormonal and intracellular signaling pathways and pH dependent allosteric modifications. SNATs are implicated in many physiological processes associated with reciprocal transcellular amino acid exchange, cellular nutrition, and metabolite secretion/detoxification pathways (Mackenzie and Erickson, 2003).

5.9.8.3. Vesicular GABA Transporters, vGATs (SLC32)

These transporters mediate vesicular accumulation of inhibitory neurotransmitters via an H^+/GABA(Gly) exchange (see Section 5.9.3.6.1). They presently comprise a single-member "family" in mammals designated SLC32 (Gasnier, 2003), which in insects represents a single level transition between A and N system transporters within the SLC38 family and proton amino acid transporters of the SLC36 family (**Figures 6** and **9**). A single vGAT gene encodes at least one splicoform in each dipteran model. The physiological role of vGATs is in vesicular accumulation of intracellular GABA, which is essential for inhibitory chemical signaling. Essential and universal throughout the Metazoa, inhibitory neurotransmission implicates a stabilizing

selection that would conserve vGAT sequences and would make it reasonable to identify insect vGAT genes by phylogenetic relevance with mammalian genes (**Figures 6 and 9**). Hence, the function of *An. gambiae* EAAT05252 and *D. melanogaster* NP_610938 in vesicular GABA uptake can be considered.

5.9.8.4. Proton Amino Acid Transporters, PAT (SLC36)

Proton amino acid transporters (PATs) comprise a group of electrophoretic H^+/amino acid (1 : 1) symporters that mediate cytosolic acquisition of small neutral amino acids from intracellular (lysosomal) and extracellular proteolysis. In mammals, the PAT group is represented by four genes that encode two well-characterized transporters, PAT1/LYAAT-1 and PAT2, and two orphan transporters (Boll *et al*., 2003a). The first orphan has been characterized as a rat brain-specific lysosomal amino acid transporter (rLYAAT-1) (Sagne *et al*., 2001) and also as a mouse intestinal epithelium-specific plasma membrane proton/amino acid transporter (mPAT1), which induces H^+ driven, low affinity ($K_m^{G,A,P} = 7$, 7.5, 2.8 mM) transport of Gly, Ala, Pro, and several structurally related derivatives in *Xenopus* oocytes (Boll *et al*., 2002). In contrast, PAT2 has a narrower substrate selectivity and higher affinity ($K_m^{G,A,P} = 0.59$, 0.26, 0.12 mM) (Boll *et al*., 2002). PATs are differentially and broadly expressed in mammalian tissues except for the orphan PAT3, which so far has been found only in adult mice testis (Boll *et al*., 2003b). Immunocytochemical studies show that rLYAAT-1 is associated with other cellular membranes, e.g., Golgi apparatus, ER, and occasionally with the plasma membrane (Agulhon *et al*., 2003).

Dipteran genomes comprise nine putative genes in *An. gambiae* and 11 genes, encoding 15 identified transcripts, in *D. melanogaster*. These transporters split into five orthologous groups within the dipteran framework; one additional paralogous group is present in *D. melanogaster* (**Figure 9**). However, the entire population of these dipteran transporters is paralogous to mammalian PATs.

The phylogeny of SNATs and PATs apparently reflects transitions of electrochemical properties observed among characterized transporters in these families. Such transitions were suggested earlier as an evolutionary trend from an H^+ driven ancestral carrier, e.g., in PATs and vGAT, toward aquisition of a Na^+ driven mechanism, e.g., in SNATs (Boll *et al*., 2003a; Chen *et al*., 2003). An inverse evolutionary trend, from a Na^+ dependent ancestral mechanism toward a H^+ driven mechanism, is apparent from the phylogenetic analysis. Although H^+ driven mechanisms are indeed older; the SNATs and PATs population is self-rooted and apparently shares a common ancestor with the Na^+ driven SNF (SLC6) transporters (**Figure 6**). This fact means that Na^+ driven mechanisms were already established before the SNAT and PAT families diverged. In addition, a Na^+ driven mechanism is encoded in the older A system of SLC38 transporters that reside on the plasma membrane (**Figures 6 and 9**). The ability to modify properties under low intracellular Na^+ demand (N system SLC38) and directly utilize proton motive forces (SLC36) presumably was acquired later during the establishment of phagocytosis and lysosomal digestion in earlier eukaryotes. SLC36 members residing in various endomembranes correspond with lysosomal traffic for which the apical intestinal membrane is just a single possible position. Paralogous clustering in insect and mammalian SLC36 is not surprising, since this group is under the pressure of diverse nutrient requirements in different tissues and cell types. In contrast, vGAT (SLC 32) serving in inhibitory neurotransmission evolved under a stabilizing pressure, which is reflected by its trans-specific orthology. Despite structural similarity, SLC32 and SLC36 exhibit striking differences in their kinetic mechanisms: SLC32 vGAT is an exchanger (antiporter) utilizing H^+ motive forces from synergetic activity modulated by Cl^- channels and V-ATPase for ligand accumulation (Gasnier, 2003), whereas SLC36 is a symporter utilizing both H^+ and ligand electrochemical motive forces for ligand secretion through lysosomal membranes and/or ligand uptake through plasma membranes (Boll *et al*., 2003a).

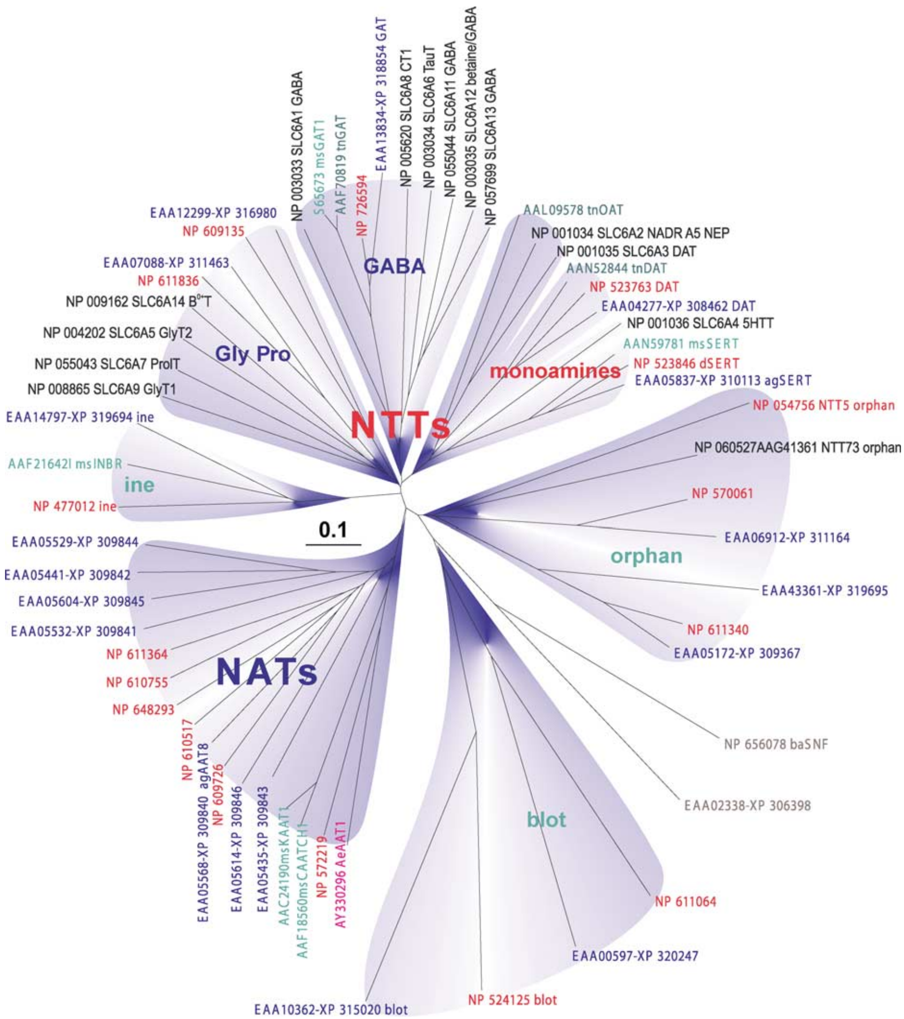
5.9.8.5. Sodium Neurotransmitter Symporter Family (SNF; SLC6)

The title of this amino acid transporter family, which is present in many protein databases, reflects a historical, rather than a biological, perspective. It is misleading in four ways. First, the root of this family is located among primitive primordial carriers that have broad substrate selectivity and apparently share a common ancestor with archaeal and bacterial transporters (**Table 1**). Second, members of at least five other, phylogenetically remote, families participate directly in neurotransmitter transport, namely, EAATs (SLC1), PATs (SLC36), vGAT (SLC32), vGluTs (SLC17), and vMAT (SLC16). Third, the SNF family includes a large number of nutrient amino acid transporters (NATs) and undefined transporter functions (blot, ine) along with the neurotransmitter transporters (NTTs) (See **Figures 6 and 10**; **Table 1**). Fourth, electrochemical

mechanisms encoded in these transporters can utilize transmembrane gradients for ions other than just Na^+ and/or Cl^-, e.g., K^+. Nevertheless, all SNF members share significant similarities in their sequences and secondary structures, which include 12 relatively conserved TMDs and a large extracellular loop between transmembrane domains 3 and 4, although prominent differences are present in this loop.

5.9.8.5.1. Neurotransmitter transporters, NTTs The following subsets of insect Na^+/Cl^- neurotransmitter transporters (SNF) are described above: GABA transporters (GAT; Section 5.9.3.4.1); dopamine transporters (DAT), octopamine transporters (OAT), and serotonin transporters (SERT or 5HTT; Section 5.9.3.4.2); glycine-proline transporters (Section 5.9.3.4.3); inebriated transporters (Ine; Section 5.9.3.4.4) (See also Sections 5.9.2 and 5.9.3).

5.9.8.5.2. Nutrient amino acid transporters (NATs) NATs represent a large and phylogenetically separate cluster of carrier proteins with specific physiological roles in insects and apparently in many other organisms. Here a new scheme of SNF classification that includes two subfamilies, NTTs and NATs (**Figure 10**) is introduceed. Phylogenetic analysis revealed six NAT genes in the *D. melanogaster* genome and seven genes in the *An. gambiae* genome (**Figures 6 and 10**). The properties of four currently cloned and characterized insect NATs, *M. sexta* KAAT1 and CAATCH1,



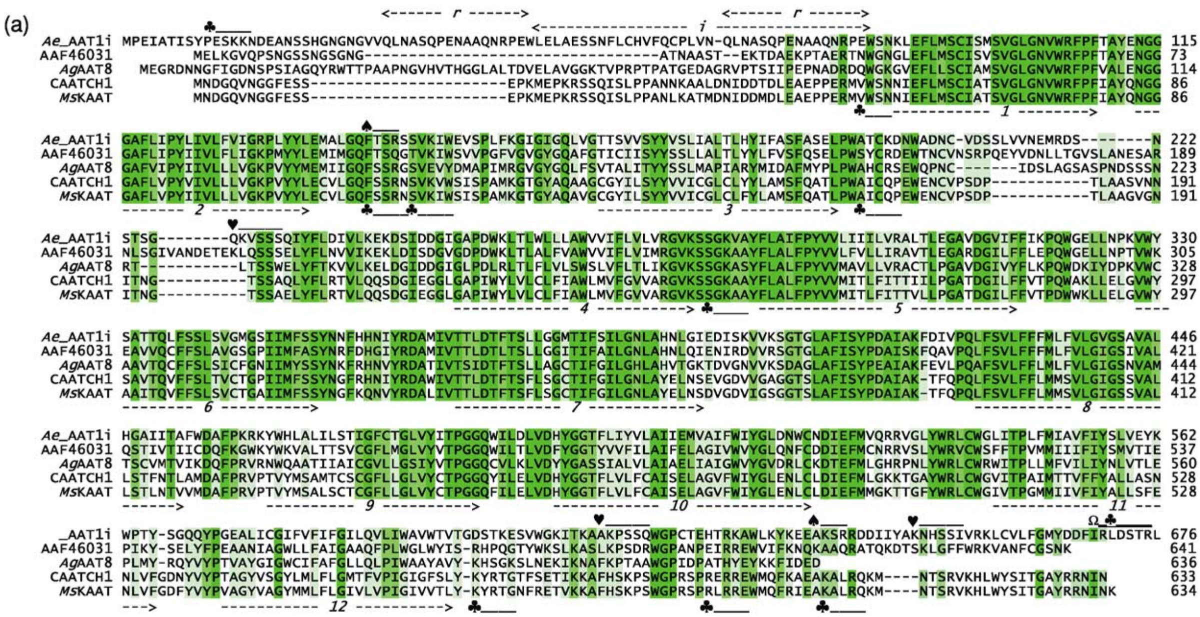


Figure 10 Unrooted neighbor-joining dendrogram of insect and mammalian neurotransmitter transporters (NTTs) and nutrient amino acid transporter (NATs) from the sodium neurotransmitter family (SNF, SLC6). Font colors: blue, *An. gambiae* sequences; red, *D. melanogaster* sequences; black, *H. sapiens* sequences; dark green, *T. ni*; light green, *M. sexta*; brown, bacterial SNF related transporter from *Bacillus anthracis* (NP_656078) and *An. gambiae* sequence, which apparently is symbiotic contamination (EAA02338). Scale bars are evolutionary distances in mutations per site.

Ae. aegypti AeAAT1 (Boudko *et al*., in press), and *An. gambiae* agAAT8, are reviewed here. Cloned insect NATs share common 12-TMD's secondary structure and high homology in protein sequences (**Figure 11**).

msKAAT1, a potassium and sodium ion coupled amino acid transporter, was the first NAT in the SNF family to be cloned. Efforts to clone it based on phylogenic proximity to the NTT cluster were unsuccessful and it was cloned by extensive heterologous expression-screening of RNA fractions from posterior midgut of *M. sexta* (Castagna *et al*., 1998). Because the msKAAT1 sequence is significantly similar to that of other SNF members, it is clear that the SNF category includes not only transporters for neurotransmitter uptake but also other transporters that mediate epithelial functions. *Xenopus* oocytes expressing KAAT1 induced uptake of neutral amino acids but not charged ones or GABA, resembling in this profile mammalian system B carriers (Castagna *et al*., 1998) as well as the earlier reported amino acid uptake in brush border vesicles from midgut epithelium of *M. sexta* (Hennigan *et al*., 1993a, 1993b). (Sequence similarities are shown by the intensities of the green background.) Ae_AAT1 specific and universal homologous protein features are shown in upper and lower lines, respectively, as follows: ← # → similar transmembrane domains and their numbers; ← r →, internal sequence repeats; ← i →, insert that is absent in alternative Ae_AAT1 (AAN40410); ♣, protein kinase; C, phosphorylation sites ($n=10$); ♠, cGMP dependent protein kinase phosphorylation sites ($n=2$); ♥, myosin 1 heavy chain kinase phosphorylation sites ($n=3$); Ω, protein kinase C phosphorylation sites of all types ($n=1$). (b) Reciprocal amino acid sequence identity matrix. (c) Hydropathy plot and predicted transmembrane topology of all five transporters (TopPed II parameters were: GES-hydrophobicity scales; 1.0 upper and 0.5 lower cutoffs; 10 and 5, respectively; core and wage window sizes, 60; critical loop length, 2 for critical transmembrane spacer. Hydropathy values (vertical scale) and distribution of transmembrane spanning domain (insert at bottom) are aligned relative to amino acid position (horizontal scale).

the vesicle studies, msKAAT1 utilizes not only Na^+ but K^+ gradient as well. K_m^{K+} (1 mM Leu) = 32 ± 2.8 mM, which was five times higher than K_m^{Na+}. The high expression of msKAAT1 in absorptive columnar cells of the posterior midgut, which was confirmed by Northern blots and *in situ* hybridization, as well as the unusual mechanism that is adapted for K^+ rather than Na^+ motive forces for amino acid translocation, fits with the physiology of nutrition in caterpillar larvae, which have a low Na^+ and high K^+ plant diet. In addition, studies of pH dependency showed that msKAAT1 transport efficiency is maximal in the alkaline media that is physiologically normal for caterpillar midgut (Peres and Bossi, 2000).

Reciprocal ligand inhibition experiments show that msKAAT1 substrates require the presence of both the carboxylic group and the alpha-amino group, as well as the uncharged side chain (Vincenti *et al.*, 2000). The unique characteristics of msKAAT1 suggested that its inhibitors would represent a new type of lineage selective, and thus environmentally safe, insecticides and encouraged further analysis of its electrochemical, pharmacological, and structural properties. These studies led to several important findings, e.g., the ability of heterologous msKAAT1 to induce carrier coupled and uncoupled ion fluxes with specific ion selectivity profiles (Bossi *et al.*, 1999a, 1999b), the key role of the Y147 site in substrate selectivity and affinity (Liu *et al.*, 2003), the critical role of the E93 site in the functional folding of msKAAT1 (Sacchi *et al.*, 2003), and the irreversible pharmacological inhibition of msKAAT1 by modification of the R76 residue with an arginine-modifying reagent, phenylglyoxal (Castagna *et al.*, 2002).

msCAATCH1, a nutrient amino acid transporter that is also an ion channel, was cloned by a PCR based strategy using degenerate primers to conserved peptide motifs in the msSNF but avoiding msKAAT1-specific motives (Feldman *et al.*, 2000). In contrast to msKAAT1 and NTTs, the *Xenopus* oocyte expressed msCAATCH1 is Cl^- independent but combines a carrier associated current with a carrier independent leakage current, which can be blocked by methionine, alanine, leucine, histidine, glycine, and threonine. In addition, msCAATCH1 exhibits different substrate selectivity depending upon symported cations, e.g., preferring threonine in the presence of K^+ but preferring proline in the presence of Na^+ with apparent $K_m^{[Na+]Pro} = 330$ versus $K_m^{[Na+]Tre} = 35$ and $K_m^{[K+]Pro} = 1900$ versus $K_m^{[K+]Tre} = 235$ in μM, respectively. Simultaneous assay of isotope labeled amino acid uptake and voltage clamped currents revealed that transport and ligand gated channel mechanisms are thermodynamically uncoupled (Quick and Stevens, 2001). msCAATCH1 and msKAAT1 share 90.6% peptide sequence identity and could be alternative splicoforms of a single gene. In addition, they share the essential role of Y147 in the ligand affinity (Stevens *et al.*, 2002) along with the analogous role of Y140 in GAT1 (Bismuth *et al.*, 1997). Despite this striking structural similarity, the two msNATs encode transporters that are dramatically different in physiological and electrochemical properties. Hopefully, future studies of the relative expression and membrane location will clarify the physiological roles of these two transporters in the caterpillar midgut.

aeAAT1, the first NAT to be cloned from a mosquito larva, was cloned from a larval posterior midgut cDNA collection of the Yellow fever mosquito, *Ae. aegypti* (Boudko *et al.*, in press) using a PCR based similarity cloning approach (Feldman *et al.*, 2000) followed by rapid amplification of cDNA ends (RACE). Complete analysis revealed that aeAAT1 serves as a primary phenylalanine provider in mosquito larvae (Harvey *et al.*, 2003). Despite remarkable sequence similarity with msKAAT1 and msCAATCH1, the substrate and electrochemical profiles of aeAAT1 differ from the lepidopteran transporters. For example, the Cl^- dependency and ability to utilize both K^+ and Na^+ electrochemical gradients that are characteristic of msKAAT1 are absent in aeAAT1 (**Figure 12**). Additional screening of an entire-larval cDNA collection indicated the presence of two splicoforms, short (aeATT1) and long (aeAAT1i). Heterologous expression/characterization in *Xenopus* oocytes confirmed that long splicoform aeAAT1i is a low-affinity and high-throughput transporter with a specific preference for phenylalanine (substrate affinity profile F >> C > H > A ≈ S > M > I > Y > T ≈ G > N ≈ P > L-DOPA > GABA > L >> DA ≈ Octopamine ≈ 5HT; $K_m^{Phe} = 0.45$ mM; $K_m^{Na+} = 38$ mM; $\eta Na^+/\eta Phe \approx 2/1$; **Figure 12**). Whole mount *in situ* hybridization confirmed a specific spatial transcription of aeAAT1 in the posterior midgut, salivary glands, cardia, and specific basal cells of gastric caeca (**Figure 13**).

Although aeAAT1 shares some properties with msNATs and the well-known mammalian B^{0+} system, for which the molecular identity so far consists of but one cloned transporter (Sloan and Mager, 1999), differences in substrate affinity and electrochemical profile, which apparently are a result of intensive adaptive divergence, make uncertain the possibility of defining a clear orthology between NAT species. Two other insect transporters that mediate aromatic amino acid uptake are members

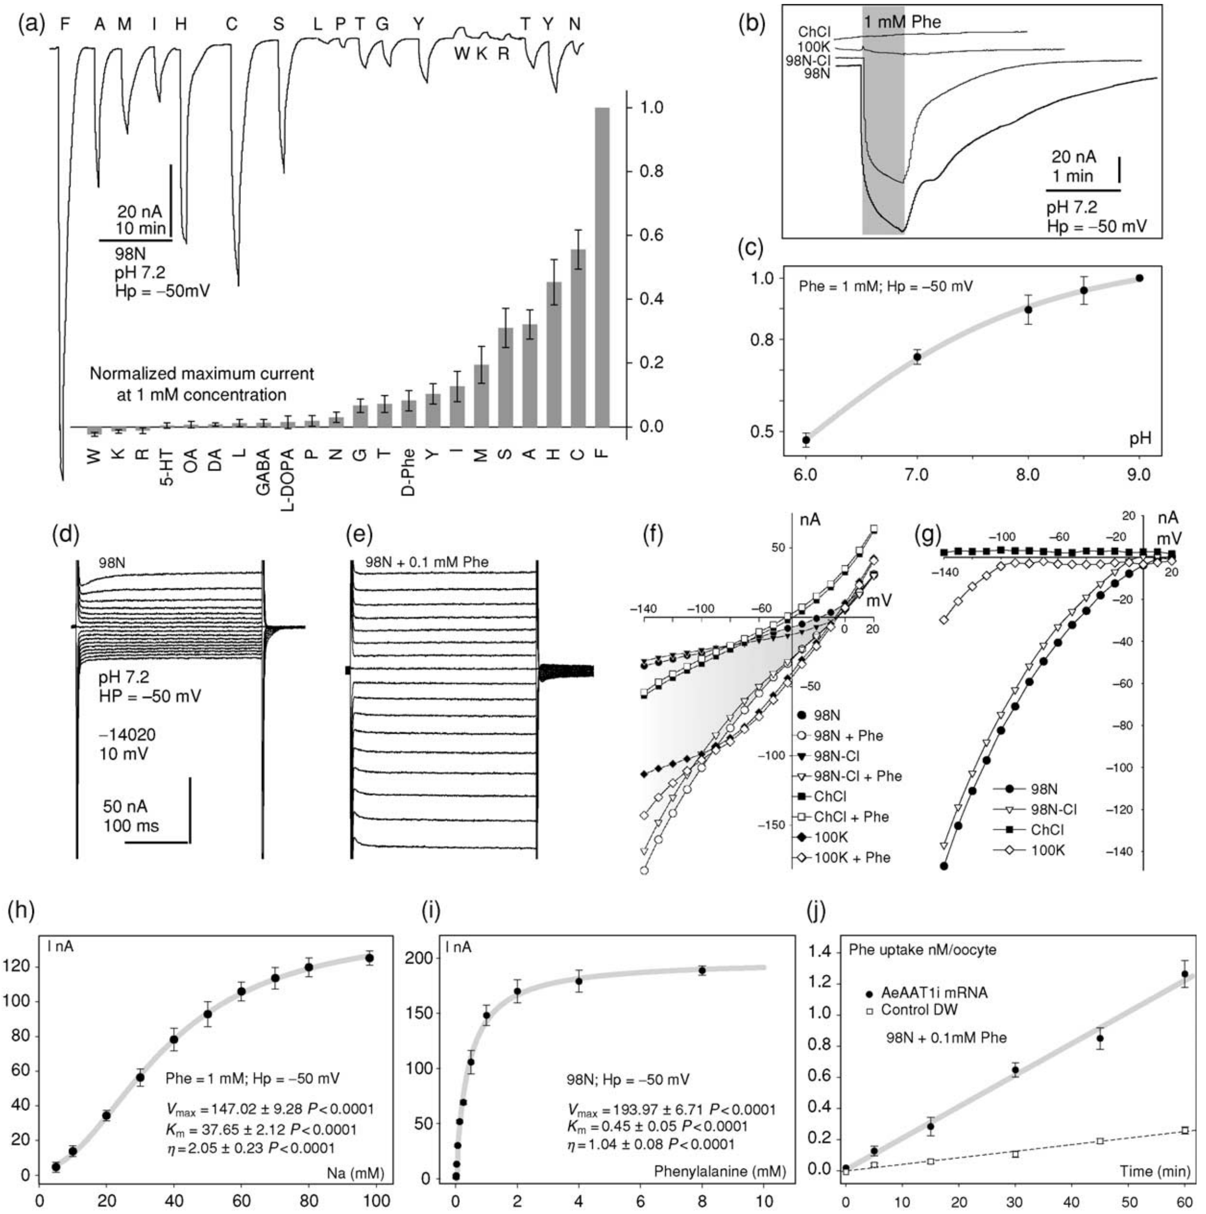

Figure 12 Electrochemical properties of Ae_AAT1i expressed in *Xenopus* oocytes. (a) Top: a trace representing amino acid induced currents in an oocyte injected with Ae_AAT1i mRNA (all amino acids were presented at 1 mM final concentration in 98 mM Na^+-containing saline at pH 7.2 for 30 s and washed until complete recovery of the background current). Bottom: amino acid and selected neurotransmitter sensitivity profiles in heterologously expressed Ae_ATT1i (bars are means of normalized responses ± SE; $n \geq 3$ for different oocytes). of the Na^+ independent TAT (Kim *et al.*, 2001) transport systems and heterodimeric LAT^+4F2hc group (Mastroberardino *et al.*, 1998; Rossier *et al.*, 1999), which are well characterized in mammals (SLC16 and $SLC7^+$SLC3 and SLC16 phylogenetic families, respectively). An increasing number of studies indicate that TAT and heterodimeric transport systems participate in the basolateral epithelial uptake/exchange of various organic solutes in growing cells (Verrey *et al.*, 2003). By contrast, aeAAT1

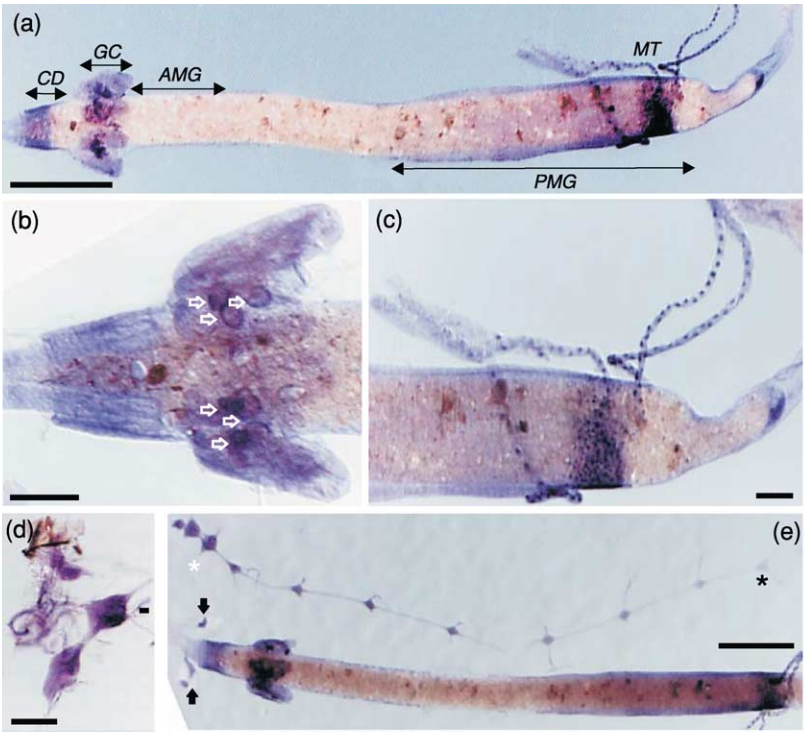

Figure 13 *In situ* hybridization of whole-mount early 4th instar *Ae. aegypti* larvae with Ae_ATT1i DIG mRNA probes. (a) Distribution of Ae_AAT1i (blue labeling). and other NATs appear to play a prominent role in the primary uptake of essential nutrient amino acids from the lumen to the epithelial cells through the apical brush border membranes in posterior midgut. aeAAT1 is also transcribed in the cardia and gastric caeca, where amino acid absorption is likely, because amino acids in these tissues are extensively depleted by the polymerization of the peritrophic matrix in the lumen of the cardia. These data support the hypothesis that aeAAT1 is a key transporter in phenylalanine-consuming pathways, such as the dopaminergic neurotransmission and ectoderm tanning pathways that are ubiquitous in the animal kingdom, as well as in insect-specific external cuticle sclerotization and polymerization of the peritrophic matrix.

agAAT8 (resembling predicted gene product EAAT05568) was cloned from larvae of *An. gambiae*, which serve as a genomic and tropical disease vector model. A novel, high throughput strategy was used for cloning and characterization of this transport protein (Boudko *et al.*, unpublished data). This strategy combines cyberanalysis to verify the correct 5′ and 3′ open reading frame (ORF) ends with PCR cloning from a high performance, tissue specific-cDNA collection (Matz, 2002) using long, ligation-ready, ORF-flanking primers and the efficient expression vector, pXOOM, which is designed for heterologous expression in *Xenopus* oocytes or mammalian cell lines (Jespersen *et al.*, 2002). In contrast to aeAAT1, agAAT8 has approximately equal apparent affinity for products of phenylalanine catabolism, including tyrosine and L-DOPA ($K_m^Y > 0.3$ mM). Although *in situ* hybridization revealed similar expression patterns for both mosquito transporters, some differences are prominent, e.g., the relative labeling intensity of aeAAT1 is significantly higher in the posterior midgut than in the gastric caeca, whereas labeling of agATT8 is approximately equal in the two regions. The transcript density of both transporters also varied depending upon developmental stage.

In summary, from the information currently available on insect NATs we conclude that this group comprises transporters that mediate the initial absorption of essential nutrient amino acids from the midgut lumen into the epithelial cells of the mosquito. Nutrient amino acid transporters do not possess the trans-specific orthology exhibited by neurotransmitter transporters (**Figures 6 and 10**), since they diverge through extensive gene duplication and losses during adaptation to particular environmental and nutrient niches. Most likely, similar paralogous groups of nutrient transporters will be defined in other insects and will be split into several, probably three, subclusters, each of which is adapted to transport an isomorphic subset of amino acids. In addition to encoding principal apical transporters, NATs may encode basolateral transporters through an alternative splicing of an anchoring motif. Owing to their crucial role in insect nutrition and phylogenetic specificity, NATs are considered to be excellent targets for the development of lineage-specific and environmentally safe mosquitocides.

5.9.8.5.3. Orphan transporters: transitions between SNF clusters These transporters are essential for physiology and development but their substrates and transport mechanisms are currently undefined. Reasons for failure to characterize orphan transporters could vary, e.g., inappropriate heterologous system, incorrect protein folding, or lack of function enabling interactions. Phylogenetic analysis indicates that orphan species represent functional and presumably evolutionary transitions between groups with defined functions (**Figure 6**). For example, orphan *ine* transporters represent a transition between neurotransmitter transporters and nutrient amino acid transporter subfamilies. SNF orphans cannot be defined as a subfamily since they do not form a true separate cluster but instead represent several consecutive levels in the phylogenetic tree. One orphan gene, named by similarity with a mammalian orphan group, has been extensively analyzed in *Drosophila* (Johnson *et al.*, 1999). This gene, named bloated tubules (*blot*), exhibits a complex and dynamic expression pattern during embryogenesis of supporting processes that are essential for cell division, differentiation, and epithelial morphogenesis. The analysis showed five putative orphan genes in *An. gambiae* and four genes encoding seven presently known isoforms in *D. melanogaster*, which represent transitions between SNF and PAT (proton amino acid transporters) superfamilies (**Figure 3**).

5.9.9. AAT Cluster IV (SLC15, SLC16, SLC17, SLC18)

Cluster IV represents one of the most diverse groups of transporters, many of which do not transport amino acids but are phylogenetically close to those which do so (**Figure 6**). It corresponds to distantly related families of mammalian transporters, including: vesicular acetylcholine and monoamine transporters (vAChT and vMATs, SLC18, see also Section 5.9.3.3.2). It is the best characterized group of vesicular transporters. It includes monocarboxylate cotransporters (MCTs, SLC16), which comprise one characterized T-type amino acid transporter (TATs, SLC16A10), H^+/oligopeptide transporters (OPTs, PEPTs, SLC15), and vesicular glutamate transporters (vGluTs). The latter represent a family that is united with transporters of type I phosphate and other organic and inorganic anions (SLC17). Since these transporters have not been characterized in insect lineages we include the most comprehensive subset of predicted genes from dipteran genomes in the phylogenetic analysis.

5.9.9.1. Vesicular Monoamine and Acetylcholine Transporters, vMATs and vAChT (SLC18)

The SLC18 family comprises specific transporters mediating high-affinity vesicular accumulation of biogenic amines that are essential for cholinergic and aminergic transmission in CNS and neuromuscular synapses throughout the Metazoa (Eiden *et al.*, 2003). These transporters apparently are not related to amino acid carriers but are included here because they are functionally similar to vesicular amino acid carriers from other phylogenetic groups (vGAT, SLC32 and vGluT, SLC17) and show distant relationships to monocarboxylate transporters (MCT, SLC16), with at least one member serving as an amino acid carrier. More direct phylogenetic links with SLC18 have been defined with toxin-extruding antiporters (TEXANs) (Yelin and Schuldiner, 1995), which are abundant in bacteria, fungi, and Archaea (**Table 2**) (Paulsen and Skurray, 1993). In bacteria these transporters appear to be essential components of interspecific antibiotic tolerance and drug resistance (Schuldiner *et al.*, 1994; Schuldiner *et al.*, 1995). All metazoan transporters that are involved in neuronal signaling are highly conserved structurally, and SLC18 members are no exception. They share remarkable similarities, in sequences and electrochemical signatures, with different lineages of the Metazoa (Rand *et al.*, 2000). A different, though highly conserved, SLC18 member's electrochemical

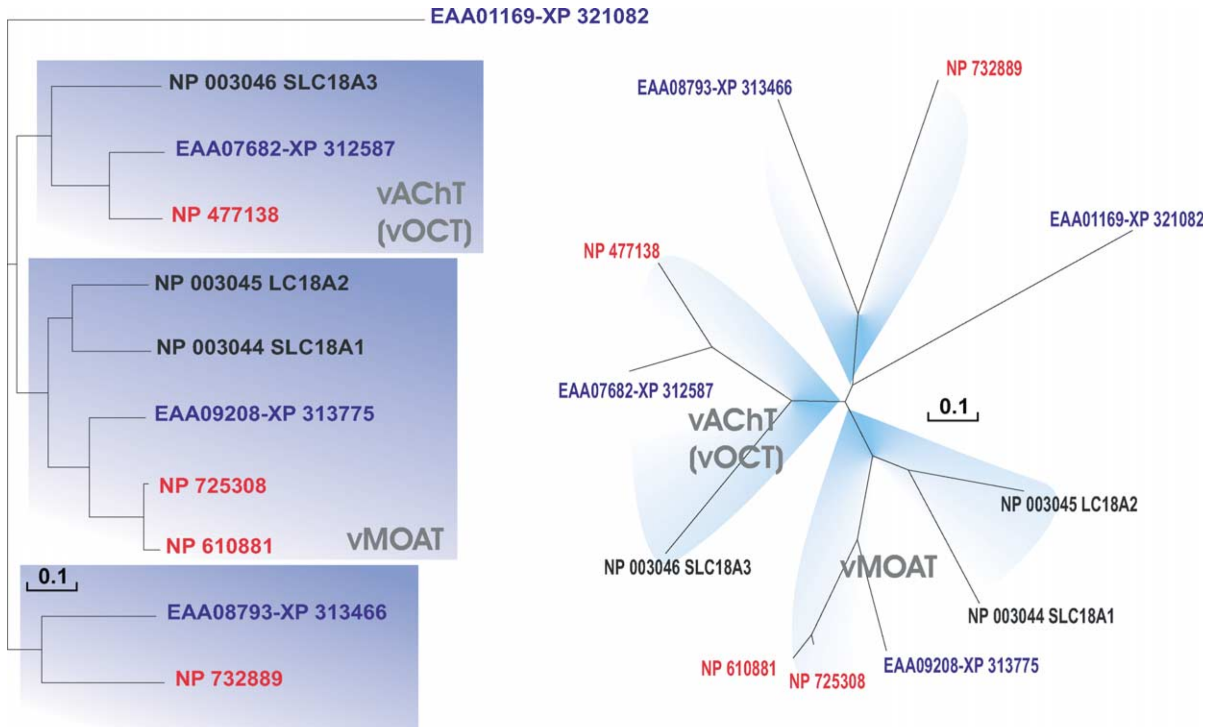

Figure 14 Phylogenetic proximity of dipteran and mammalian vesicular monoamine transporters (vMOATs; SLC18). Unrooted phylogram (left) and dendrogram (right). Font colors: blue, *An. gambiae* sequences; red, *D. melanogaster* sequences; black, *H. sapiens* sequences. Scale bars are evolutionary distances in mutations per site.

mechanism enables a high-affinity uptake of biogenic amines, which is thermodynamically coupled to H^+ V-ATPase generated proton motive forces. It exhibits a rigid stoichiometry of 1 ligand per $2H^+$ and is capable of vesicular accumulations to as high as 0.5 M concentrations of particular ligands, exceeding up to 10^3-fold and 10^5-fold transmembrane gradients for ACh and monoamines, respectively (Parsons, 2000).

Although many mammalian SLC18 members have been analyzed since the first rodent vMAT1 and vMAT2 (SLC18A1 and SLC18A2, respectively) was cloned (Erickson *et al.*, 1992; Liu *et al.*, 1992b), only one SLC18 related insect transporter has been cloned from *D. melanogaster* (NP_477131 or AAB86609; Kitamoto *et al.*, 2000a). A 12-TMD structure for this transporter has been predicted. However, since experimental proof is lacking, an alternative 10-TMD model, arising from a different prediction algorithm, can be considered as well (Rost, 1996; Eiden *et al.*, 2003). Based on EM and immunolabeling, dmvAChT colocalized with acetylcholine transferase in the brain of the adult fly where it appears to mediate specific components of synaptic wiring in glomerula (Yasuyama *et al.*, 2002). vMATs and vAChTs are encoded by four putative genes in the *An. gambiae* and three genes in the *D. melanogaster* genomes (Figures 6 and 14). vMATs and vAChTs form orthological clusters with mammalian SLC18 members. In contrast to the *H. sapiens* genome, only one gene encodes vMAT in dipteran genomes; however, two apparent splicoforms are encoded by dmvMAT (Figure 14). An additional dipteran specific group is absent in mammalian SLC18 (Figure 14).

5.9.9.2. Monocarboxylate Transporters and T System Amino Acid Transporters, MCTs and TATs (SLC16)

MCTs and TATs (SLC16) comprise a large family of H^+ coupled transporters and apparent uniporters (Bonen, 2000) that currently includes 14 members (Halestrap and Meredith, 2003) in *H. sapiens*, which, within the E value interval selected for these sequences, could be associated with 18 predicted gene products in NCBI and EMBL databases (Figure 15). Only five mammalian SLC16 members have been characterized (Halestrap and Meredith, 2003):

1. The first member was defined *in vivo* (Deuticke, 1982), subsequently cloned (Kim *et al.*, 1992; Garcia *et al.*, 1994), and designated MCT1 (SLC16A1); when heterologously expressed, it

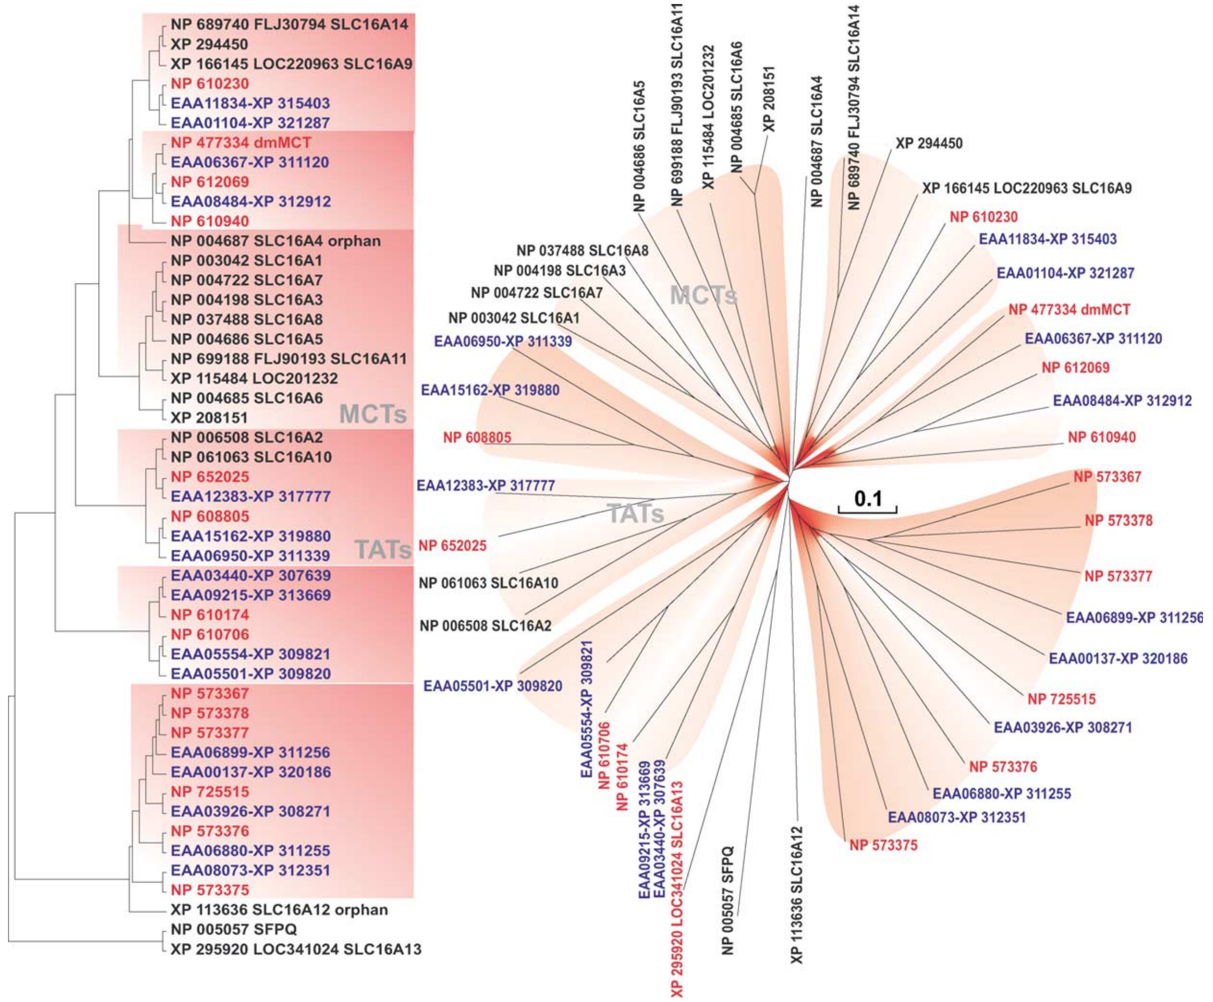

Figure 15 Phylogenetic distribution of dipteran and mammalian monocarboxilate and T-system amino acid transporters (MCTs and TATs; SLC16). Rooted cladogram (left) and unrooted dendrogram (right). Human orphan member of SLC16 (SLC16A13) and PTB associated splicing factor (NP_005057) are selected as outgroup. Font colors: blue, *An. gambiae* sequences; red, *D. melanogaster* sequences; black, *H. sapiens* sequences. Scale bars are evolutionary distances in mutations per site.

mediates a moderate affinity uptake of two to five carbon chain aliphatic monocarboxylates, e.g., $K_m^{pyruvate} = 0.7$ mM, $K_m^{propionate} = 1.5$ mM, and $K_m^{\text{L-lactate}} < 3$ mM (Broer *et al.*, 1998a; Manning Fox *et al.*, 2000).

2. Unlike MCT1, MCT2 (SLC16A2) expression intensity varies greatly in different mammalian models, e.g., its transcripts are weakly expressed in human (Price *et al.*, 1998) but are abundant in rodent (Garcia *et al.*, 1995; Jackson *et al.*, 1997) tissues where it induces a relatively high-affinity carrier; $K_m^{\text{L-lactate}} \approx 0.1$ mM and $K_m^{pyruvate} \approx 0.7$ mM (Lin *et al.*, 1998; Broer *et al.*, 1999).
3. MCT3 (SLC16A8), initially cloned from chick retinal pigment epithelium (Yoon *et al.*, 1997), mediates a low-affinity ($K_m^{\text{L-lactate}} > 6$ mM) basal transport (Yoon *et al.*, 1997; Philp *et al.*, 2001), which together with an apical MCT1 (Bergersen *et al.*, 1999) comprises a transepithelial pathway in the retinal pigment epithelium and choroid plexus.
4. MCT4 (SLC16A3) is abundant in various tissues (Price *et al.*, 1998; Wilson *et al.*, 1998; Pilegaard *et al.*, 1999; Dimmer *et al.*, 2000; Bergersen *et al.*, 2002; Meredith *et al.*, 2002) and has the weakest substrate affinity among MCTs, e.g., measured $K_m^{lactate}$ and $K_m^{pyruvate}$ values with different assay techniques are in the tenths millimolar range (Dimmer *et al.*, 2000; Manning Fox *et al.*, 2000).
5. T system transporter TAT1 (SLC16A10) mediates H^+ and Na^+ uncoupled, submillimolar affinity, active transport or facilitated diffusion of aromatic amino acids and some related metabolites (L-phenylalanine, L-tryptophan, L-tyrosine, and L-DOPA) across basolateral membranes of intestinal and renal epithelial cells as well as

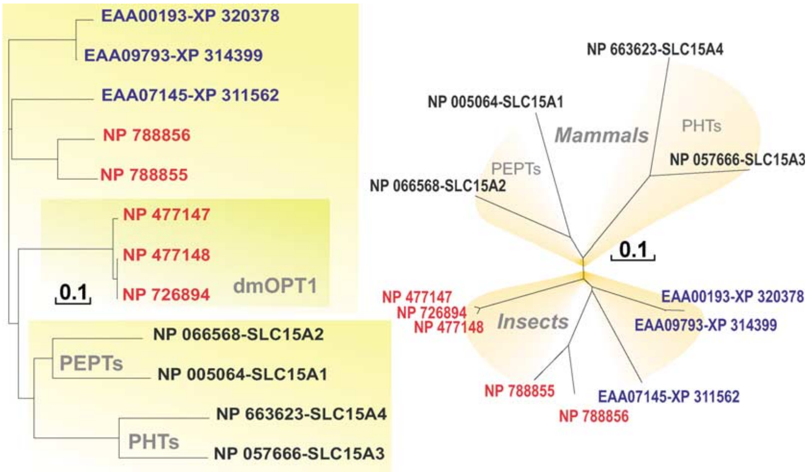

Figure 16 Paralogous distribution of dipteran and mammalian oligopeptide transporters (OPTs, SLC15). Unrooted phylogram (left) and dendrogram (right). Font colors correspond: blue, *An. gambiae* sequences; red, *D. melanogaster* sequences; black, *H. sapiens* sequences. Other abbreviations: dmOPTs, *D. melanogaster* oligopeptide transporters; PEPTs, *H. sapiens* peptide transporters; PHTs, *H. sapiens* peptide/histidine transporters. Scale bar is evolutionary distances in mutations per site.

plasma membranes of various nonpolarized cells, e.g., in placenta, liver, and muscle (Kim *et al*., 2001, 2002; Kim do *et al*., 2002). (SLC16A3 TATs should not be confused with sulfate transporter Tat1 (SLC23A11) (Toure *et al*., 2001; Vincourt *et al*., 2003) or bacteria/yeast specific TAT1 permeases (Bajmoczi *et al*., 1998)).

The tissue distributions of a few other members of SLC16 have been analyzed (Price *et al*., 1998) but no electrochemical and ligand data are yet available. A recent comprehensive review aids our SLC16 description by mentioning that heterologous expression of a TAT1 related SLC16A2 transporter in *Xenopus* oocytes revealed a thyroid hormone (T4 and T3) transporter phenotype, which has micromolar apparent substrate affinity and appears to be independent of sodium and proton motive forces (Halestrap and Meredith, 2003).

All characterized SLC16 members have a 12-TMD structure with a characteristic cytosolic loop between TMDs 6 and 7. At least some members require an auxiliary protein for trafficking and functional coordination in plasma membranes, e.g., MCT2 interacts with an unknown protein factor (Kirk *et al*., 2000) and MCT1 and MCT4 interact with CD147 (also known as OX-47, extracellular matrix metalloproteinase inducer (EMMPRIN), HT7, or basigin) (Kirk *et al*., 2000; Zhao *et al*., 2001; Halestrap and Meredith, 2003), which was confirmed using a fluorescence resonance energy transfer (FRET) technique (Wilson *et al*., 2002) and by reduction of transport by antisense silencing of a CD147 ortholog in *Xenopus* oocytes (Meredith and Halestrap, 2000).

Phylogenetic analysis discloses 15 putative genes in *An. gambiae* and 14 genes, corresponding with the number of identified transcripts, in *D. melanogaster* (Figures 6 and 15). One member of *D. melanogaster* MCTs was identified before annotation of the genome (CAB42050); however, it does not cluster with mammalian MCT1 (SLC16A1) but instead fits into an apparently orthologous phylogenetic cluster with four other putative members of dipteran MCTs (Figure 15). In fact, most MCTs form mammalian or dipteran lineage specific, paralogous clusters, except for orphans SLC16A9 and SLC16A14 and the characterized aromatic amino acid transporter TAT (SLC16A10) and putative thyroid hormone transporter (SLC16A2), which show proximity with dipteran transporters and would reasonably be expected to have similar physiological roles (Figure 16).

5.9.9.3. Oligopeptide Transporters, OPTs (SLC15)

Oligopeptide transporters (OPTs), also known as peptide transporters (PTRs) (Steiner *et al*., 1995) evolved as an efficient, energy-saving uptake mechanism complementing or replacing amino acid carriers in special cases, e.g., (1) they enable high throughput intracellular loading of nutrient amino acids in peptide form and (2) they remove specific and nonspecific oligopeptides, which may interfere with cellular signaling and cellular interactions from body fluids and subcellular media. In mammals,

OPTs mediate H^+ coupled uptake of small peptides or similar substrates into intestinal and renal epithelial cells, bile duct epithelium, glial and epithelia cells of the choroid plexus, lung, and mammary gland (Daniel and Kottra, 2003). OPTs mainly utilize transmembrane proton motive forces and appear to be reversible when heterologously expressed in HeLa cells or *Xenopus* oocytes (Fei *et al.*, 1994; Boll *et al.*, 1996) and *in vivo* (Tomita *et al.*, 1995).

The first proton-coupled peptide transporter PEPT1 (SLC15A1) was identified by expression-cloning from rabbit small intestine cDNA in the Hediger laboratory (Fei *et al.*, 1994). It mediates the uptake of small peptides, being independent of extracellular Na^+, K^+, and Cl^- gradients and, surprisingly, independent of the membrane potential as well. PEPT1 is transcribed in intestine, kidney, and liver with small amounts in brain. Simultaneously, PEPT1 was cloned by Murer and colleagues in attempts to define the molecular basis for proton-dependent peptide transport in BBMV from rabbit small intestinal epithelia (Boll *et al.*, 1994). This group also cloned an orthologous transporter PEPT2 (SLC15A2) from kidney cortex epithelia which, in contrast to low-affinity high-throughput PepT1, mediates high-affinity low-throughput transport of a virtually identical subset of substrates (Boll *et al.*, 1996). A large number of PepT1 and PEPT2 related OPTs have been identified by homology cloning in subsequent years (Liang *et al.*, 1995; Saito *et al.*, 1996; Rubio-Aliaga *et al.*, 2000; Chen *et al.*, 2002; Verri *et al.*, 2003), including one from insects, i.e., *D. melanogaster* OPT-1 (Roman *et al.*, 1998). More recently, two other OPTs were identified in mammals: a brain-specific peptide histidine transporter 1 (rat PHT1 a.k.a. human PTR4, SLC15A4; Yamashita *et al.*, 1997) and peptide histidine transporter 2 (rPHT2 a.k.a. hPTR3, SLC15A3) isolated from the rat lymphatic tissue (Sakata *et al.*, 2001). In contrast to the broad substrate affinity of PEPT1 and 2, PHT1 and 2 have more specific sets of substrates including histidine and some model di- and tripeptides. These transporters apparently play different, more specific physiological roles, since they are strongly expressed in specialized tissues such as brain for PTH1 (Yamashita *et al.*, 1997) and lymphatic system, lung, spleen, and thymus for PHT 2 (Sakata *et al.*, 2001). OPTs range from 450 to 700 amino acid residues, most of the eukaryotic members having ~650 amino acid residues and 12 predicted TMDs with cytoplasmic N- and C-termini (Daniel and Kottra, 2003).

5.9.9.3.1. *Drosophila* oligopeptide transporters, OPTs The only insect OPT characterized to date is from *D. melanogaster* (Roman *et al.*, 1998). The *opt* gene encodes a protein that mediates proton-dependent di- and tripeptide transport in intestinal and Malpighian tubular (renal) epithelia. Like mammalian OPTs, fruit fly OPT1 has 12 TMDs and a long (200 amino acid residue) fifth external loop. It is most similar to human renal PEPT2 and intestinal PEPT1 proteins, containing the highly conserved histidine residue, thought to be involved in peptide binding and transport, at position 88.

Up to 30% of total amino acids in the hemolymph of adult fruit flies are present in the form of di- or tripeptides, which serve in osmoregulation (Chen, 1966; Collett, 1976). Protein digestion in *Drosophila* occurs mainly in the midgut where resulting peptides and amino acids are rapidly taken up by the epithelium (Law *et al.*, 1977) and metabolized or transported to the hemolymph. Hemolymph amino acids are secreted into the Malpighian tubular lumen (equivalent to vertebrate glomerular filtration) but are reabsorbed in the hindgut. Compared to mammalian peptide transporters discussed above, little was known about the absorption of peptides in insects prior to the cloning of dmOPT1. The *opt1* gene encodes a high-affinity di- and tripeptide transporter that is proton dependent. It is transcribed in germinal and somatic tissues of both males and females where it is most highly expressed in nurse cells of the ovary. It is also expressed in epithelial cells of the midgut and rectum and is mildly expressed in neurons. Uptake was assayed in HeLa cells transfected with pCMVOPT1 or pCMV2 using lipofectamine. Tritiated L-alanylalanine uptake was measured in buffer with high NaCl and low KCl at pH 6.0. Evidence that the peptide transport is proton-coupled was a ten-fold decrease in uptake when extracellular pH was increased from 6 to 7 and a 20-fold decrease when it was increased from 6 to 8. Uptake was virtually abolished by FCCP (25 μM), which collapses the proton gradient. The K_m for OPT1-dependent alanylalanine transport at external pH = 6 was 48.8 μM (Roman *et al.*, 1998).

5.9.9.3.2. Phylogenetic characteristics of dipteran OPTs OPT (SLC15) related transporters are present in most life kingdoms, except for the Archaea (**Table 2**), being especially abundant in plants where they are in phylogenetic proximity to nitrate transporters. OPTs comprise three putative genes in the *An. gambiae* genome and three genes in the *D. melanogaster* genome with three different

splicoforms known for the single characterized example of a dmOPT1 gene (**Figure 16**). Within the framework of mammalian and dipteran lineages, OPTs form separate paralogous branches, indicating relatively recent gene duplication. Probably for the same reason, the proximity of different dipteran OPTs is difficult to deduce solely from the phylogenetic analysis.

5.9.9.4. Vesicular Glutamate and Phosphate Transporters, vGLUTs and P_iTs (SLC17)

In mammals, the SLC17 family comprises two physiologically distinct groups of characterized transporters: type I inorganic phosphate transporters (P_iTs) and vesicular glutamate transporters (vGLUTs). The P_iT family, which was initially restricted to transporters of inorganic phosphates across plasma membranes, has now been expanded to include transporters of various organic and inorganic anions across both plasma membranes and endomembranes. The vGluT family comprises extensively analyzed vesicular glutamate transporters, which are specialized to serve excitatory neurotransmission that enables endomembrane traffic and vesicular accumulation of excitatory amino acids. Since no SLC17-related insect transporter has yet been characterized, only a brief description of known SLC17 transporters was included from a recent comprehensive review (Reimer and Edwards, 2003).

5.9.9.4.1. Inorganic phosphate transporter, type I P_iTs (SLC17A1) The first member of mammalian SLC17A1 (NaP$_i$-1) was identified by expression cloning from a rabbit kidney cortex cDNA library, based on its ability to induce Na^+-dependent phosphate transport in *Xenopus* oocytes, with 750-fold higher apparent uptake than controls injected with total poly(A) RNA (Werner *et al.*, 1991). However, submillimolar substrate affinities of rabbit NaP$_i$-1 and the next-cloned ortholog from *H. sapiens* (Miyamoto *et al.*, 1995), as well as specific electrochemical properties of their heterologous expression in *Xenopus* oocytes, e.g., conductance for mineral and organic anions (Busch *et al.*, 1996a, 1996b; Broer *et al.*, 1998b) and low pH sensitivity (Busch *et al.*, 1996b), do not match characteristics of Na^+-dependent P_i uptake in brush border membrane vesicles (Amstutz *et al.*, 1985) and do not support a primary role for these transporters in high-affinity phosphate transport (Murer *et al.*, 2000; Reimer and Edwards, 2003). Indeed, two different P_iT types have been identified (Magagnin *et al.*, 1993; Kavanaugh *et al.*, 1994) that are unrelated to SLC17 Na^+/P_i^- cotransporters. One new type is a SLC34 family, type II P_iT, whose members mediate apical P_i uptake in various polarized epithelia (Murer *et al.*, 2003). Transporters of the other new type were originally described as retroviral receptors (Olah *et al.*, 1994) but are now recognized as type III P_iTs (SLC20), which appear to be basolateral components of P_i homeostasis (Collins *et al.*, 2003). A recent revision of P_iTs tends to support the earlier proposal that some members of the SLC17 family are facultative P_iTs, with major roles in the rapid acquisition of electrochemical and pH balance via anion secretion (Amstutz *et al.*, 1985). In fact, they may utilize a variety of electrochemical mechanisms ranging from facilitated diffusion to electrophoretic Na^+ coupled symport (Reimer and Edwards, 2003).

Intriguingly, despite a crucial role of P_i homeostasis in all organisms, and the presence of homologous proteins in other metazoa, as well as in bacteria, fungi, and plant lineages, there is no trace of SLC20 and SLC34 families in dipteran genomes and they appear to be absent in arthropods in general. Conversely, mammalian type I P_iTs do not include any dipteran sequences (**Figure 17**), which leaves uncertain the presence of SLC17 related P_iTs in dipteran genomes.

5.9.9.4.2. Sialin (SLC17A5) Extensive genetic analysis and BBMV studies revealed a physiological role for another SLC17 member, sialin (SLC17A5), which apparently mediates lysosomal H^+ coupled (1 : 1) emission of amino carbohydrates (sialic acid) from lysosomal catabolism of glycosylated membrane proteins, as well as serving endomembrane traffic of some monocarboxylic acids (Reimer and Edwards, 2003).

5.9.9.4.3. vGlutT (SLC17A6, 7, 8) Three members of mammalian SLC17 (SLC17A6, A7, and A8, a.k.a. vGluT1, 2 and 3) are recruited in excitatory neurotransmission, enabling vesicular storage of L-glutamate. Initially defined as plasma membrane, Na^+ coupled P_iTs, vGluT1 (Ni *et al.*, 1994), and vGluT2 (Aihara *et al.*, 2000) transport phenotypes have since been shown to be H^+ coupled carriers that mediate accumulation of L-glutamate into synaptic vesicles of neurons (Bellocchio *et al.*, 2000) and glutamatergic endocrine cells (Hayashi *et al.*, 2001; Takamori *et al.*, 2001). All characterized vGluTs have been morphologically associated with glutamatergic neurons of the postnatal brain and especially abundant at membranes of synaptic vesicles, although spatial differences in subtype distribution in the brain are prominent (Bellocchio *et al.*, 1998; Fremeau *et al.*, 2002; Varoqui *et al.*, 2002b). The neuronal specificity of vGluTs makes them

useful markers of excitatory neuronal components, e.g., recent demonstration of the existence of peripheral glutamatergic components in the gastroenteropancreatic system and testis (Hayashi *et al*., 2003). The expression of vGluTs occurs very early in embryogenesis (Gleason *et al*., 2003). High resolution immunoelectron microscopy also demonstrates a specific subcellular distribution of vGluT types, e.g., vGluT1 and vGluT2 are mainly associated with nerve terminals; in contrast, vGluT3 is present in vesicular structures of astrocytes and neuronal dendrites (Fremeau *et al*., 2002).

Apparently, all vGluTs share highly conserved, pmf driven, electrochemical mechanisms with nearly millimolar apparent K_m^{Glu}. Like P_iTs, vGluTs enable Cl^- and some other anionic conductances in BBMV and heterologous models (Bellocchio *et al*., 2000; Fremeau *et al*., 2001; Varoqui *et al*., 2002a). Vesicular glutamate accumulation has been shown to be inhibited by the broad specificity blocker of chloride conductance DIDS(4,4′-diisothiocyanatodihydrostilbene-2,2′disulfonic acid). Like all other endomembrane transporters, electrophoretic vGluTs are energized by electrogenic V-ATPase.

5.9.9.4.4. Phylogenetic characteristics of SLC17 transporters Before their molecular identities were established, P_iTs and vGluTs have been identified by comparative studies of vesicular glutamate uptake in BBMVs from neuronal tissues of several vertebrates and invertebrates (goldfish, frogs, turtles, pigeons, rats, fruit fly, and crayfish). Their

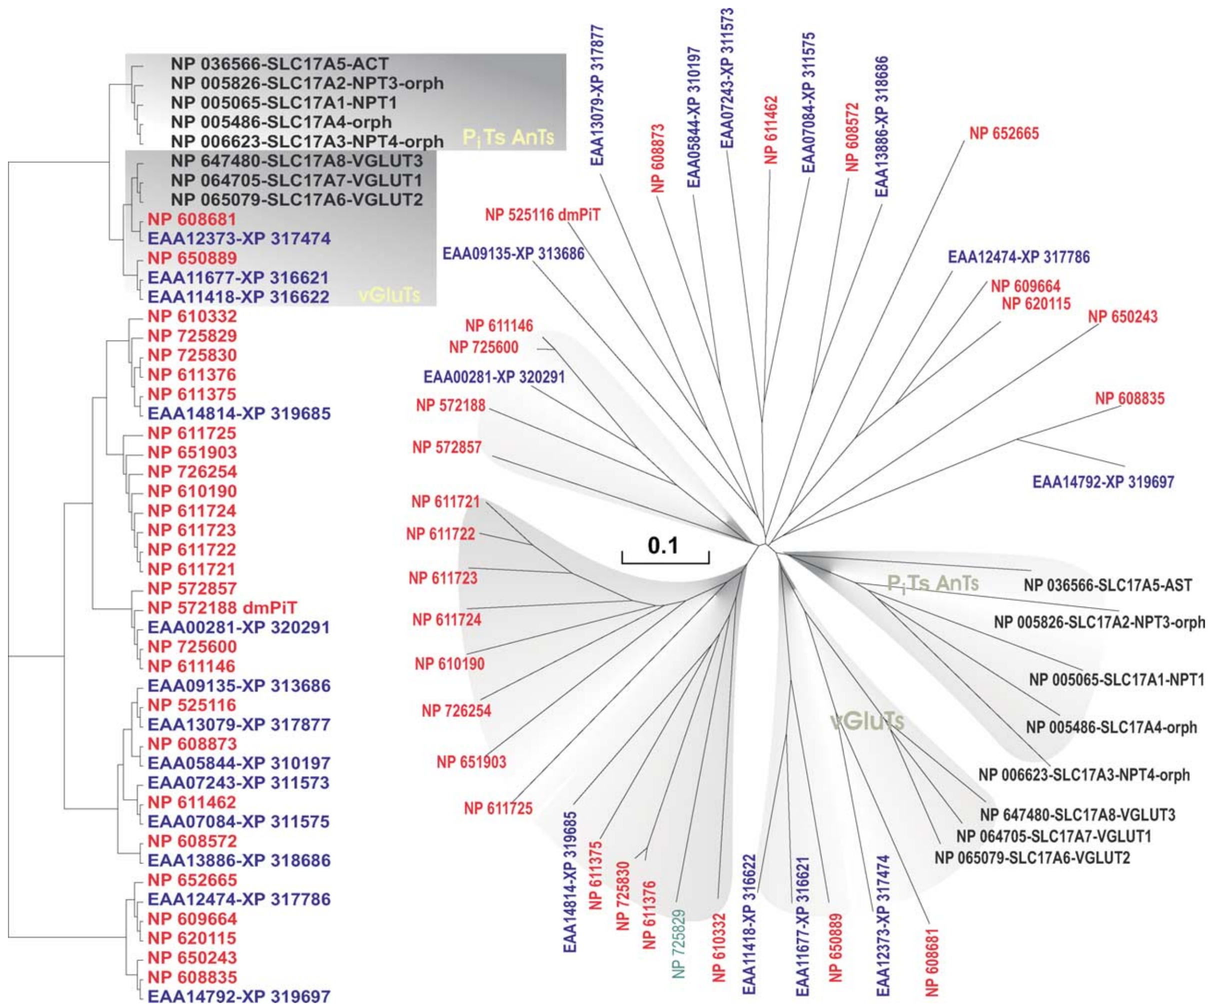

Figure 17 Phylogenetic proximity of putative organic and inorganic anion (P_iTs) and vesicular glutamate transporters (vGluTs) in dipteran and mammalian models (SLC17). Unrooted cladogram (left) and dendrogram (right). Other abbreviations: AST, anion/sugar transporter; NPT, sodium inorganic phosphate transporter[4]. Scale bars are evolutionary distances in mutations per site.

[4]NTP title reflects a historical drawback, since NTPs were initially cloned and characterized as inorganic phosphate transporter Type I. Later, the major role of this transporter phenotype in the transport of organic and inorganic anions was established.

properties, including millimolar Glu affinity, as well as V-ATPase energization and chloride stimulation, appear to be extremely conserved over 350–400 million years (Tabb and Ueda, 1991). Phylogenetic analysis indicates a single gene copy in *D. melanogaster* and *An. gambiae* genomes with close proximity to three, apparently paralogous, vGluT gene clusters in mammals (**Figure 17**). Two additional *An. gambiae* genes and one *D. melanogaster* gene are more distantly related to the vGluTs. No dipteran genes with proximity to P_iT transporters have been found to date. The earlier defined dmP_iT transporter gene (NP_572188) now appears to be phylogenetically separated from P_iT gene clusters; its function cannot be deduced from the phylogenetic pattern alone. Intriguingly, dipteran genomes include several new SLC17 gene clusters that are absent in mammals and have no matches with characterized genes in other lineages. Two of these clusters indicate remarkable gene duplications in *D. melanogaster* (**Figure 17**). In summary, relatively conserved VGluTs seem to have diverged through lineage-specific gene duplications that reflect increases in functional and morphological complexity of the CNS. Hence, a role for the genes that encode transporters related to the SLC17 family can be expected in insect vesicular glutamate homeostasis. In contrast, P_i absorption and homeostasis, which are essential for all organisms, appears to occur in insects through phylogenetically unrelated roots of transporters that are distinct from P_iTs of SLC20, SLC34, and even SLC17.

5.9.10. Summary and Perspectives

Practical benefits from characterizing neurotransmitter and nutrient amino acid transporters have extraordinary relevance to medicine and agriculture. The kinetic properties, abundance, variety, and uniqueness of NTTs and NATs make them prime targets to develop inexpensive insecticides and mosquitocides that are as potent as DDT and as safe as Bti (*Bacillus thuringiensis* subsp. *israelensis*). As providers of intracellular amino acids, plasma membrane transporters represent rate limiting components of crucial metabolic pathways. Low concentrations of high affinity or irreversibly binding inhibitors can block transport and abolish essential pathways, so such transport inhibitors may be potent insecticides. The abundance and variety of transport systems in insects provides a plethora of targets for potential amino acid transport inhibitors. This diversity may help to avoid the pitfalls of resistance that have doomed many previous insecticides such as DDT – before pests become resistant to one transport inhibitor another one can be developed. In particular, the unique nature of mosquito NATs provides the potential for agents to be developed that will inhibit them without affecting vertebrate or other insect NATs and NTTs. The most likely class of potential mosquitocides would be amino acid derivatives and peptides. An almost infinite variety of such compounds can be synthesized and screened making use of new tools from recent advances in insect transport physiology and molecular biology. Vincent Wigglesworth invented Insect Physiology to help control tropical diseases. Today, integrative physiology and functional genomics of *An. gambiae* and other disease vectors can build on this basic science to provide rational strategies for impacting insect borne diseases through vector modification to reduce disease transmissibility and insecticide application to reduce vector population size.

5.10.1. Introduction

5.10.1.1. Historical Perspective

Esterases have been a major part of insect biochemical research over the last 50 years. As an important component of insects' xenobiotic defence system, they have long been a focus for studies of chemical insecticide metabolism and resistance. Additionally, acetylcholinesterase (AChE) was a target for the early organophosphate (OP) and carbamate compounds. Other esterases have been implicated in the metabolism of specific hormones and pheromones and, consequently, in various aspects of insect development and behavior. Many esterases are easily scored by isozyme electrophoresis, with multiple isozymes and their high levels of genetic variation making them tractable, informative tools for a variety of biochemical and ecological genetic studies. For all these reasons esterase biochemistry featured prominently in the first edition of *Comprehensive Insect Biochemistry, Physiology and Pharmacology* in 1985.

At that time not a single insect esterase gene had been cloned but in the decade that followed several were isolated, particularly from *Drosophila*. The insect esterase genes cloned in this period all proved to derive from the one gene family, the carboxyl/cholinesterases (or just carboxylesterases in

the Pfam nomenclature – see Pfam ID 00135). Members of this family were also cloned from various prokaryotes and vertebrates, albeit some of the noninsect esterase genes cloned in the period clearly belonged to different gene families. Alternatively, genes for several noncatalytic proteins involved in various signaling processes in insects and other eukaryotes were found to be members of the carboxyl/cholinesterase gene family.

Critically too, the tertiary structures of AChE and some sequence-related microbial lipases were resolved in this period and shown to lie within the one structurally defined superfamily of proteins. This defining structure is called the α/β hydrolase fold. Catalytically active members of this superfamily all use the same reaction mechanism, involving a catalytic triad of residues headed by a serine or sometimes cysteine residue as a nucleophil. While hydrolases (including some esterases) in some other superfamilies have the same reaction mechanism, they achieve this with otherwise unrelated structures, apparently as an outcome of convergent evolution.

The last decade has seen a few cases of esterase-based insecticide resistance resolved at a molecular level. All these cases still involve the carboxyl/cholinesterase gene family. All involve OP resistance. They fall into essentially three groups, first involving mutant AChE molecules that are less sensitive to inhibition by the insecticide, second involving many-fold amplifications of genes encoding carboxylesterases with limited ability to hydrolyze the insecticide but substantial scope to sequester it, and the third involving structural mutations in certain carboxylesterases that improve their kinetics for insecticide hydrolysis. Remarkably, some of the same mutations are found in widely different species, which might suggest very limited options for evolving resistance. Given the empirical data on the structure of AChE, and modeled structures of the carboxylesterases based on AChE and the lipases, it is becoming possible to understand the effects of the resistance mutations in precise structural terms.

Of course the other qualitative advance during the last decade has been the application of modern genomic and proteomic technologies to the study of insect esterases. This has greatly facilitated the isolation of esterase genes and improved our understanding of their functions and sequence relationships. It appears that insect species may each have about 30–60 different members of the carboxyl/cholinesterase gene family, about three-quarters of them catalytically active, and that these comprise a majority but not all of the esterase isozymes that can be visualized after native polyacrylamide gel electrophoresis (PAGE). The insect members of the family fall into a small number of clades many of whose origins approach or, in a few cases, exceed the age of the class Insecta. Within some of these clades, however, there has been remarkably rapid evolution such that only a few orthologous genes can be identified except among quite closely related species.

This chapter reviews the biochemistry and genetics of insect esterases, focusing mainly on developments since the first edition of this series. It is written from a genomics perspective and the bulk of it is organized around the major clades of insect esterases as revealed by the comparative genomic analysis. First, however, some of the historical functional definitions and classifications applied to insect esterases are briefly revised.

5.10.1.2. Functional Definitions and Classifications

The esterase reaction, defined as the hydrolysis of an ester to its component alcohol and acid, encompasses hydrolysis of a diverse range of carboxylic, thio-, phospho-, and other ester substrates. It sits within a broader set of hydrolase reactions that also include glycosylases, proteases, amidases, and many others (Webb, 1992). Even more generally it can be considered a particular case, involving water, of the acylation of a nucleophil. Use of other nucleophils in otherwise similar reactions generates, for example, various dehalogenase activities (Ollis *et al.*, 1992).

Most of the discussion in this review concerns enzymes hydrolyzing esters of carboxylic acids (E.C. 3.1.1). This is a valid and useful functional grouping insomuch as reaction energetics are significantly different for the hydrolysis of esters like thio- and phospho-esters, where there is a strong negative charge in the immediate environment of the ester bond (Aldridge and Reiner, 1972). Nevertheless, there is still great diversity even among the carboxylic acid ester hydrolases.

One major distinction separates the lipases from others in the group (Phythian, 1998; Arpigny and Jaeger, 1999; Fojan *et al.*, 2000). Lipases have maximal activity for esters like triglycerides with simple alcohol groups and complex acid moieties, which are essentially insoluble in water. Most of the others have substrates with simple acid moieties but potentially complex alcohol moieties, which are at least partly soluble in water. It is this latter, nonlipase, group, which is the particular focus of this review.

Various classifications based on inhibitor sensitivities have been applied to subdivide the nonlipase group of carboxylic ester hydrolases. One early classification in use even before isozyme studies recognized A-, B-, and C-type esterases on the basis of

their interaction with OPs. While A-type esterases could hydrolyze these molecules, the B-type enzymes were essentially irreversibly inhibited by them, and the C-type enzymes neither hydrolyzed nor were inhibited by them (Aldridge and Reiner, 1972). Most, but not all, insect esterases studied to date would be classified as B-type esterases on this scheme.

A subsequent elaboration of the Aldridge and Reiner (1972) scheme has been used to classify eukaryotic esterase isozymes detectable after native PAGE and staining with various artificial ester substrates. It relies on three classes of inhibitors, the OPs, sulfhydral reagents, and the carbamate eserine sulfate, from which can be discerned four classes of enzymes (Holmes and Masters, 1967; Coates *et al.*, 1975; Healy *et al.*, 1991). These are:

- acetylesterases, which are unaffected by any of these inhibitors and generally prefer substrates with acetyl acid groups and aromatic alcohol groups;
- arylesterases, which are only inhibited by the sulfhydral reagents and generally prefer substrates with aromatic alcohol groups;
- carboxylesterases, which are only inhibited by the OPs and prefer aliphatic esters, generally of longer acids than acetate; and
- cholinesterases, which are inhibited by OPs and eserine sulfate, and prefer substrates with charged alcohol moieties like choline esters over other aromatic or aliphatic esters.

A further classification that had been applied extensively to esterase isozymes, especially in *Drosophila* and mosquitoes, groups the enzymes according to their preferential hydrolysis of the isomeric artificial substrates, α- and β-naphthyl acetate (see Sections 5.10.4.3 and 5.10.5.1 below). This distinction is made because hydrolysis of the two isomers leads to differently colored bands when the reaction is coupled with several of the common diazo staining dyes. The classification has little value as a predictor of enzyme function and indeed allelic differences between the two preferences have been described for some isozymes. The α- and β-based nomenclatures are retained herein for some widely studied enzymes and enzyme clusters, noting, however, that in themselves they represent no broader biological distinctions.

A survey of 22 soluble *Drosophila melanogaster* esterase isozymes identified 10 carboxylesterases, six cholinesterases, and three acetylesterases, with no aryl esterases, and three isozymes not clearly classifiable on this scheme (Healy *et al.*, 1991). Surveys of the major esterase isozymes of various mosquitoes and hemipterans yield broadly similar results, albeit consistently recovering minority numbers of aryl as well as acetylesterases (VedBrat and Whitt, 1975; Casabé and Zerba, 1981; Narang and Seawright, 1982).

As noted earlier, all invertebrate carboxyl and cholinesterases that have been sequenced to date lie in the same gene family, which is therefore called the carboxyl/cholinesterase gene family (Oakeshott *et al.*, 1993, 1995, 1999; Claudianos *et al.*, 2001). No sequence information has yet been reported for invertebrate acetyl- or arylesterases, although data for a few from prokaryotes and vertebrates put them in unrelated families (Campbell *et al.*, 2003). There are also a small number of functionally defined carboxylesterases from vertebrates that do not sit in the carboxyl/cholinesterase family (Zschunke *et al.*, 1991).

Several different classes of mechanism have been described for hydrolase reactions, ranging across general acid/base, electrostatic, and covalent catalyses (Voet and Voet, 1990). They may be one or two step reactions. Some use metal ions in various capacities. However, the mechanism used by the carboxyl/cholinesterases entails a two-step reaction which is independent of metal ions and has an acyl-enzyme intermediate (**Figure 1**). The serine of the active site is made more nucleophilic than usual by interaction with a histidine residue, which itself is oriented correctly by an interaction with an acidic residue. These three residues constitute the so-called catalytic triad. Their functions are analogous to those of the well-known catalytic triad of serine proteases where the same mechanism occurs. Since the structures of the two types of protein are otherwise unrelated, their shared catalytic mechanism is assumed to reflect convergent evolution.

In the first step of this reaction mechanism the oxygen of the serine's side chain makes a nucleophilic attack on the carbonyl carbon atom of the substrate, displacing the alcohol product and forming a covalent linkage with the acyl moiety of the substrate. In the second step, the oxygen of a water molecule makes a similar attack on the carbonyl carbon, hydrolyzing the covalent acyl-enzyme link to yield free enzyme and the acid product of the reaction. It has generally been assumed that the water molecule is activated by the histidine and acid residues of the catalytic triad as described for the first, acylation step (**Figure 1**), but Thomas *et al.* (1999) and Behra *et al.* (2002) have proposed that a conserved "additional serine" might sometimes provide this function instead. Both steps require a tetrahedral transition state in which charge is moved to the carbonyl oxygen. As with serine proteases, the active site of carboxylesterases has certain

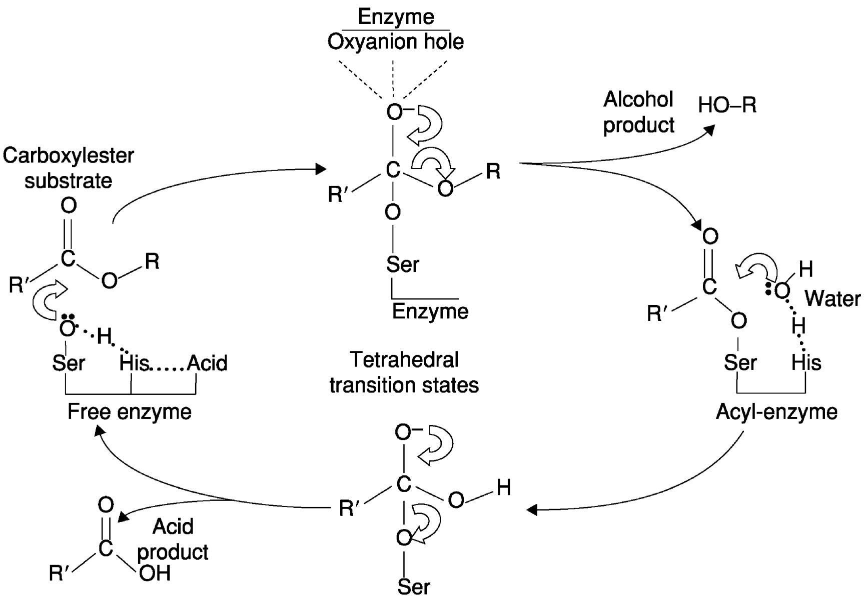

Figure 1 The carboxylesterase reaction mechanism. Carboxylesterases hydrolyze their substrates in two steps. First, the oxygen of a serine residue in the active site makes a nucleophilic attack on the carbonyl carbon of the substrate, displacing the alcohol product and forming a relatively stable acyl-enzyme. In the second step water makes a similar nucleophilic attack, this time displacing the serine residue to release the acid product of the reaction and regenerate the free enzyme. The serine of the active site is made more nucleophilic than usual by interaction with a histidine residue which is oriented correctly by an interaction with an acidic residue. During both nucleophilic substitution reactions there is a tetrahedral transition state the energy of which is reduced by an ''oxyanion hole'' in which the charge displaced onto the oxygen is accommodated by hydrogen bonding to the main-chain nitrogens of three amino acid residues around the active site. This mechanism is analogous to the mechanism of the serine proteases that also perform hydrolysis with a Ser–His–acid triad and main-chain nitrogens forming an oxyanion hole. The mechanism of serine proteases is frequently presented in detail in biochemistry textbooks with the similarity of carboxylesterases and serine proteases cited as an example of convergent evolution (e.g., Voet and Voet (1990), pp. 373–382).

conserved small residues, the main chain nitrogens of which are proposed to form an "oxyanion hole" to stabilize the transition states in both steps of the reaction by hydrogen bonding.

Hydrolysis of esters of carboxylic acids can be relatively undemanding energetically and examples of this reaction, including from the carboxyl/cholinesterases, have been described which approach diffusion limited kinetics (Taylor and Radic, 1994; Zera *et al.*, 2002; Devonshire *et al.*, 2003; Kamita *et al.*, 2003). Also, however, reactions of this type can often be relatively easily reversible, particularly in nonaqueous environments. The functional significance of the resultant esterification reactions has been well established for several bacterial "esterases," but the reverse reactions of eukaryotic esterases have received relatively little attention (Phythian, 1998).

5.10.2. Comparative Genomics of Insect Esterases

5.10.2.1. Overview

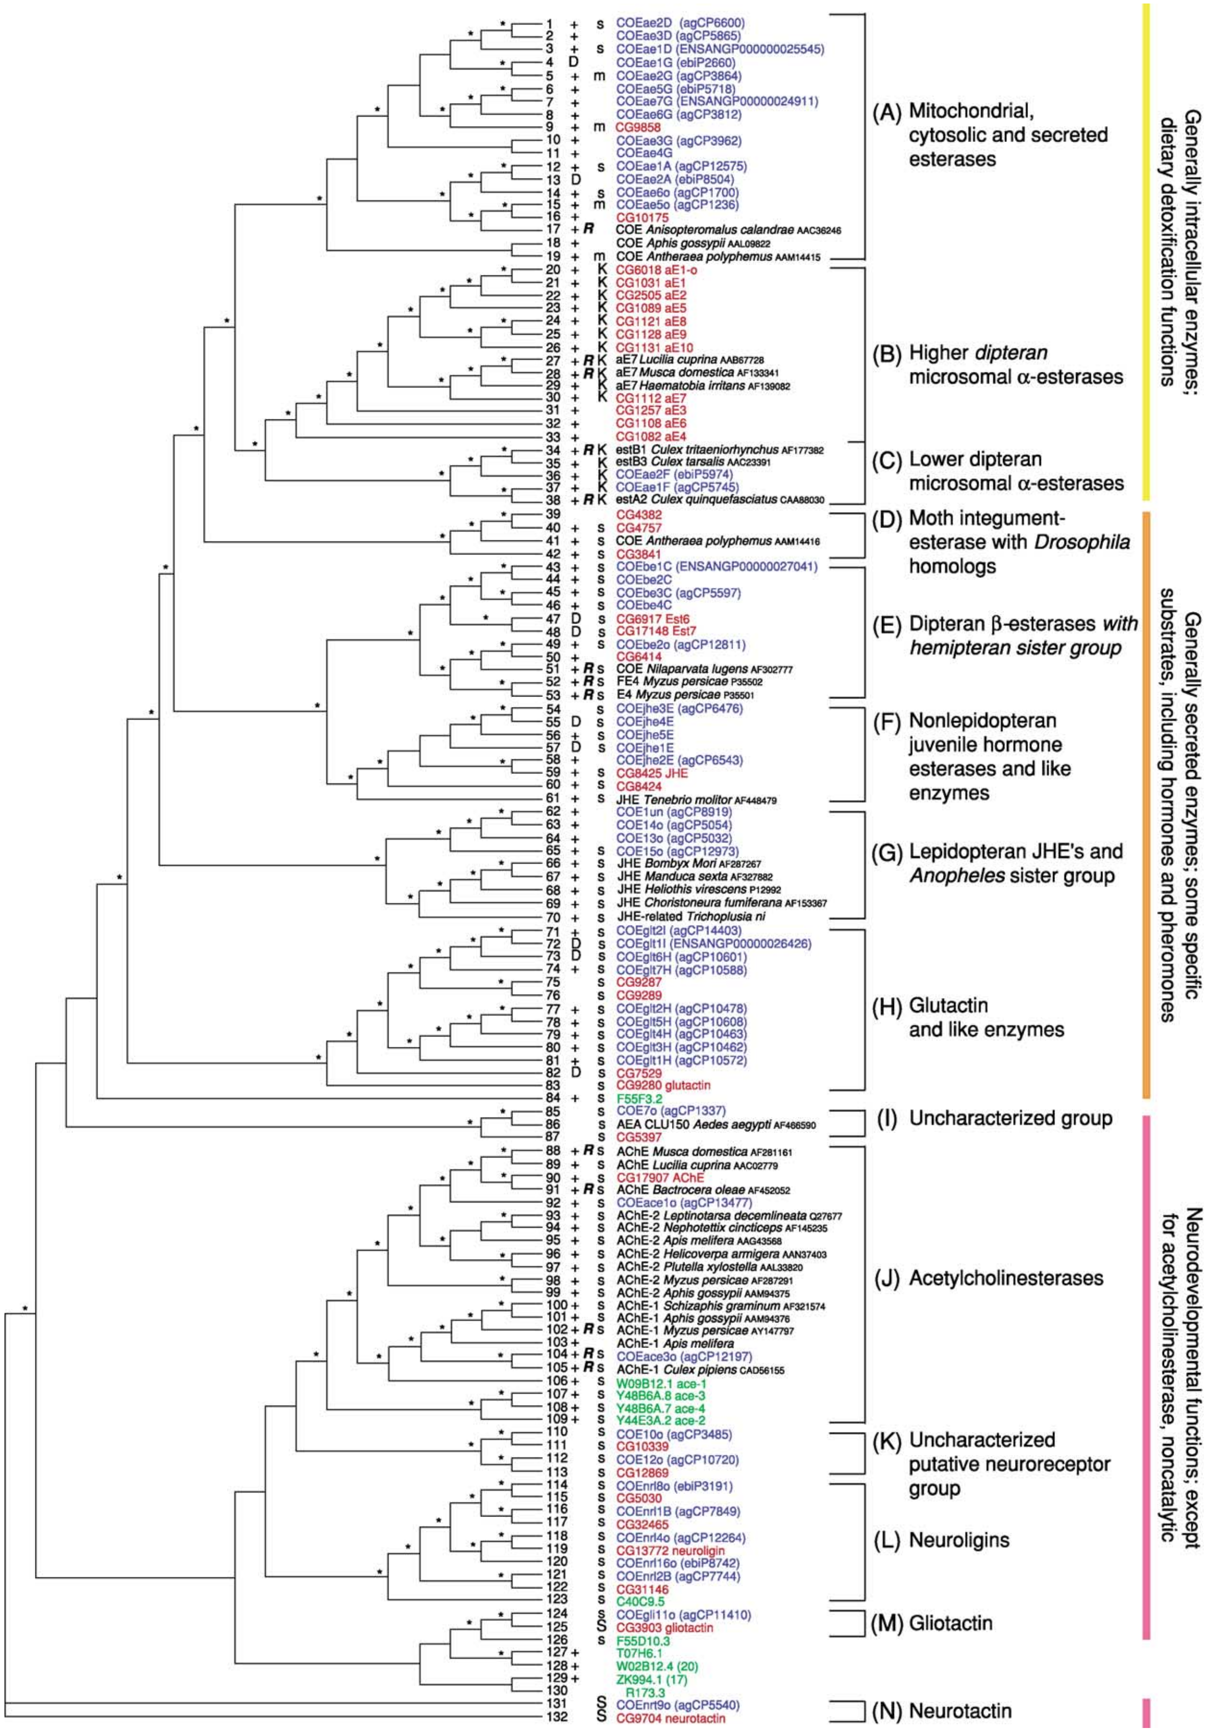
Consistent with their functional diversity, the sequences of the carboxyl/cholinesterases are also widely divergent. Even within the insect members there can be as little as about 20% amino acid identity between distant members of the family (Oakeshott *et al.*, 1999). In this and subsequent sections, it is shown how some of the sequence differences contribute to differences in the biochemistry of the proteins and their physiological functions.

Figure 2 presents a phylogeny of insect carboxyl/cholinesterase sequences. It includes all those identified in the fully sequenced *D. melanogaster* and *Anopheles gambiae* (African malaria mosquito) genomes (35 and 51, respectively), as well as 35 others for which there is both substantial sequence and some functional information from other insects. It therefore does not include the many apparently full length but functionally anonymous expressed sequence tag (EST) carboxyl/cholinesterase sequences in various insect EST databases. It also excludes several orthologs of *D. melanogaster* and *A. gambiae* sequences in other *Drosophila* and *Anopheles* species since these would simply appear in terminal bifurcations of the tree and provide little further information in terms of functional evolution. However, to give a broader context, all the lineages

of *Caenorhabditis elegans* (nematode) carboxyl/cholinesterases as identified by Oakeshott *et al.* (1999) that sit within the phylogeny (albeit for ease of tree building some nematode-specific radiations are simply represented by single sequences) are also included. Bacterial and vertebrate carboxyl/cholinesterases are not discussed, although some of their relationships to the major insect clades are known (Oakeshott *et al.*, 1999). No lipase sequences have yet been identified within the carboxyl/cholinesterase family in insects; some may sit as yet anonymously within the sequences included. However, the limited information available for insects, and the precedents in bacteria and vertebrates, suggest that most insect lipases will sit outside the clades shown in **Figure 2**, albeit many are in other families in the α/β hydrolase fold superfamily (Pistillo *et al.*, 1998; Arpigny and Jaeger, 1999; Nardini and Dijkstra, 1999; Adams *et al.*, 2000; Arrese *et al.*, 2001).

One obvious feature of the phylogeny is the high degree of separation of the insect clades from the *C. elegans* genes. There are only three clear overlaps, in the AChE, gliotactin, and neuroligin radiations. By cross-referencing the trees constructed by Oakeshott *et al.* (1999), it is also told that only these clades would likely be shared with known vertebrate carboxyl/cholinesterases. All the other clades in the phylogeny are thus insect-specific. While further sequencing may reveal representatives from other eukaryotes in some of these clades, it nevertheless seems likely that most of the insect carboxyl/cholinesterase lineages have evolved since the insects diverged from both the nematodes and the vertebrates.

The 35 non-*D. melanogaster*, non-*A. gambiae*, insect proteins in the phylogeny include 11 from other dipterans, eight from various lepidopterans, and two each from the Hymenoptera and Coleoptera, all in the Holometabola, and, for the Hemimetabola, 12 from various hemipterans. Although there are no nondipteran proteins in a few of the major clades at this point it is expected that most of these will also prove to have members from several orders, and indeed from both the Holo- and Hemimetabola, as more sequences become available. Notable here are the branch orders among the major clades; even some of the most derived clades contain members from different orders. Thus most of the major clades are older than the split between the Holo- and Hemimetabola.



For the purposes of this review the radiations in the phylogeny containing insect sequences have been partitioned into 14 major clades, denoted A to N in **Figure 2**. In the rest of this section some major sequence and structural distinctions among these clades are outlined and below (see Sections 5.10.3, 5.10.4, and 5.10.5) are reviewed what is known of the functions of proteins within each of them.

One of the major discriminants among the 14 clades is catalytic capability, as inferred from the presence of a consensus catalytic triad (see also **Figure 4** below). Significantly, there are several noncatalytic clades, including the neuroligin, gliotactin, and neurotactin lineages (clades L, M, and N), as well as two clades of uncharacterized proteins (I and K), on this criterion. As discussed later, all functional evidence from characterized members of these clades confirms their catalytic incompetence. These clades were generated at relatively early branch points in the phylogeny and, in the case of the neuroligins and gliotactins, are also known to have vertebrate orthologs (see Section 5.10.3.2). Whilst the evidence from prokaryote members of the family suggests that catalytic competence is the ancestral state (Oakeshott *et al.*, 1999), it is nevertheless clear that a few noncatalytic functions developed early in the evolution of higher eukaryotes and have been retained in diverse lineages since. Loss of catalytic activity in these clades is also associated with the acquisition of additional domains as either N- or C-terminal extensions (depending on the clade) to the single carboxyl/cholinesterase domain (**Figure 3**).

The only major clade which contains significant proportions of both presumptively catalytic and noncatalytic members is the glutactin lineage (clade H) (see Section 5.10.4.1). Functional data confirm a noncatalytic role for glutactin and, like most of the other noncatalytic proteins above, it also has extra C-terminal transmembrane and cytoplasmic domains (**Figure 3**). However, it has apparently arisen relatively recently in a lineage which is predominantly composed of catalytically active proteins and, consistent with this, it lacks vertebrate orthologs.

Interestingly, while catalytic competence is generally a good taxonomic character for the insect carboxyl/cholinesterases, the identity of the catalytic triad is not. All those with an identifiable triad use serine as a nucleophil and histidine as the base. However, the acid residue may be aspartate or glutamate, and there are several lineages within the tree where both can be found.

Cellular/subcellular localization is another taxonomically informative character, at least for much of the phylogeny. The presence of N-terminal signal peptides and/or, in many cases, direct functional information indicate that all the major noncatalytic clades contain secreted proteins, albeit those characterized are known to be tethered to the cell

Neurodevelopmental functions; except for acetylcholinesterase, noncatalytic

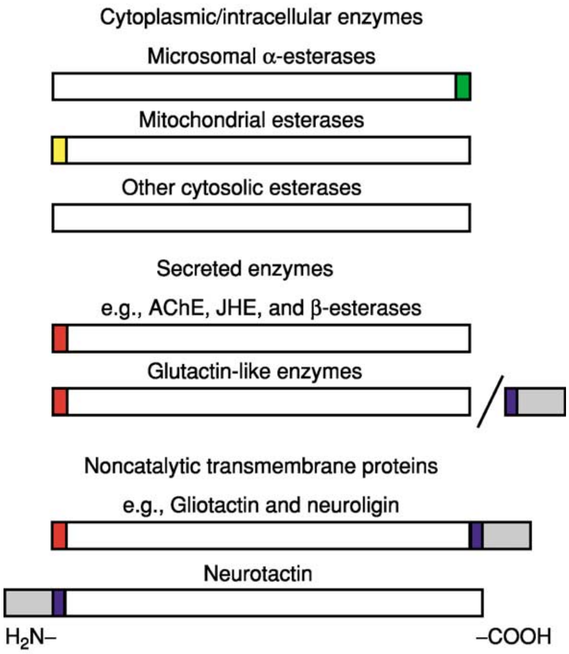

Figure 3 Schematic model (not to scale) of the consensus domain structure of insect carboxyl/cholinesterases in the various major clades indicated in **Figure 2**, showing N-terminal secretion (red) and mitochondrial targeting (yellow) and C-terminal endoplasmic retrieval (KDEL, green) signals for transmembrane proteins, the transmembrane (blue) and cytoplasmic (gray) domains. Slash symbol signifies that not all members of the glutactin clade have transmembrane domains (see Section 5.10.4.1). See also **Figure 2** regarding the secretion and endoplasmic reticulum retrieval signals.

membrane by motifs in their N- or C-terminal extensions (Figure 3) (see Sections 5.10.3.2 and 5.10.4.1). There are also some radiations of mainly catalytically competent enzymes that are secreted (D–H, J), but with the exception of glutactin and the AChE clade (J) these are not known to be membrane-associated. Members of the other major clades (A–C) are essentially all catalytically active enzymes and mostly intracellular, albeit they fall into two subgroups on the basis of subcellular localization. Members of one subgroup (B, C) can be classified as at least largely microsomal on the basis of functional data and/or the presence of C-terminal KDEL targeting motifs (Pelham, 1996; Yamamoto *et al.*, 2003). Members of the other subgroup (A) lack the latter motifs but cover a range of other localizations. A few contain conventional amino terminal secretion signals and some contain mitochondrial targeting signals (Bannai *et al.*, 2002). The rest are presumptively cytosolic, although some use of as yet unidentified nonconventional targeting signals, or extracellular translocation following membrane insertion (Emanuelsson *et al.*, 2000; Chou, 2001; Kriek *et al.*, 2003; Lai, 2003), cannot be discounted.

At the highest level, the phylogeny of insect carboxyl/cholinesterases can thus be partitioned quite cleanly into three groups on the basis of catalytic competence and cellular/subcellular localization. The oldest group (I–N) contains clades of secreted proteins that are generally membrane associated and, except for AChE, catalytically incompetent. Members of the next group (D–H) are also almost all secreted but, except for glutactin, not known to

Figure 2 Unrooted distance neighbor-joining tree showing a phylogeny of invertebrate carboxyl/cholinesterases. Sequences from the *Drosophila melanogaster* and *Anopheles gambiae* genomes (red and blue, respectively) are as annotated in Ranson *et al.* (2002). Sequences for various carboxyl/cholinesterases from other insects (black) were generally taken from the National Center for Biotechnology Information (NCBI) database; see text for inclusion criteria. The two exceptions were sequences 70 and 103, from Jones *et al.* (1994) and http://www.hgsc.bcm.tmc.edu. Sequences from the *Caenorhabditis elegans* genome (green) are as in Oakeshott *et al.* (1999) except that single representative sequences only were used for two nematode-specific lineages (see text and below). Sequences were aligned using CLUSTAL W (Thompson *et al.*, 1994) with the BLOSUM 45 scoring matrix, with gap opening and gap extension penalties of 10.0 and 0.1, respectively, followed by some minor manual corrections to conform to known structural features of carboxyl/cholinesterases. The tree was constructed with PAUP* (Swofford, 2000) using standard distances and mean character differences. Nodes with at least 50% resampling frequency in 1000 bootstrap replications are indicated with an asteriks. To the right of the tree, in order, are: sequence numbers (1–132) as used elsewhere in this paper; catalytic competence as assessed by presence of a consensus catalytic Ser–His–Glu (+) or Ser–His–Asp (D) triad; evidence of involvement in chemical insecticide resistance (R, see text), and presence of a secretion signal (s) as assessed by the iPSORT algorithm of Bannai *et al.* (2002) and, if not secreted, of a mitochondrial (m) or KDEL endoplasmic reticulum targeting signal (K) as defined by Pelham (1996) and Yamamoto *et al.* (2003). (The upper-case S for sequences 125, 131, and 132 signifies that they lack a conventional N-terminal secretion signal according to iPSORT but empirical data establish that they are presented on the extracellular side of cell membranes (see Section 5.10.3.2).) Then follow sequence names and NCBI, Celera Protein and ENSEMBL database accession numbers and, if not *D. melanogaster*, *A. gambiae*, or *C. elegans*, species names. Note that *C. elegans* sequences 128 and 129 are single representative sequences for radiations of 20 and 17 proteins, respectively. Finally, major clades of sequences recognized in the text are named (and for cross-referencing to **Figure 6** below, alphabetically identified) and three putative functional ''superclades'' are also indicated. Note that some amino terminal sequence is missing for 18 of the proteins (4, 6, 7,13, 50, 58, 62–64, 78, 80, 103, 112, 114, 116, 120, 121, 126) and some C-terminal data are missing for 17 (6, 13, 54, 58, 60, 62–65, 77–80, 95, 103, 112, 118). Note also that the recently revised nomenclature of Weill *et al.* (2000, 2002, 2003) and Russell *et al.* (2004) for the AChE sequences have been followed (see also Section 5.10.3.1).

be membrane-tethered and they are almost all catalytically competent. The third and most derived group (A–C) contains catalytically competent enzymes covering a wide range of cellular/subcellular localizations, one subgroup generally being microsomal and the remainder a mix of presumptively secreted, mitochondrial, and cytosolic enzymes.

As discussed below (see Sections 5.10.3, 5.10.4, and 5.10.5), the available functional data suggest that these three groups are also qualitatively distinct in terms of their physiological roles. Characterized members of the first group, containing the secreted, membrane-associated, noncatalytic proteins and the AChE clade, are almost all involved in neurodevelopmental processes. At least four clades in the second group, mainly composed of secreted catalytic proteins, include various hormone and pheromone esterases. Many members of the third group, comprising mainly intracellular catalytically active proteins, appear to have broad substrate specificities and more general dietary and/or detoxification functions. The mutant enzymes conferring insecticide resistance occur in all three groups: AChE enzymes resistant to OP and carbamate inhibition in the first group and pesticide detoxifying enzymes in the third and, at least for some sap-sucking insects, also in the second. First, however, the phylogeny is examined in more detail, with particular regard to some major features of tertiary structure.

5.10.2.2. The Structural Context

Figure 4 diagrams the tertiary structure of the carboxyl/cholinesterase domain of the mature AChE monomer from *D. melanogaster* (DmAChE) (Harel *et al.*, 2000) (see Section 5.10.3.1). This structure is used as a model in the following sections because it is the only insect member of the carboxyl/cholinesterase protein family whose structure has been reported to this point. There are published structures for AChEs from a few different vertebrates, for the closely related vertebrate butyrylcholinesterase (BuChE) and another vertebrate carboxylesterase, and from a few sequence-related lipases from lower eukaryotes (Schrag and Cygler, 1993; Bourne and Shindyalov, 1998; Nicolet *et al.*, 2003). The structure of the carboxyl/cholinesterase domain of DmAChE is very similar to these others in its overall organization, notwithstanding over 60% amino acid sequence divergence from them. The core of the structure is the α/β hydrolase fold, comprising a major β-sheet of 11 strands arranged in a characteristic order, plus 14 α-helices in loops situated between the strands. Also in the loops are the components of the active site and catalytic gorge

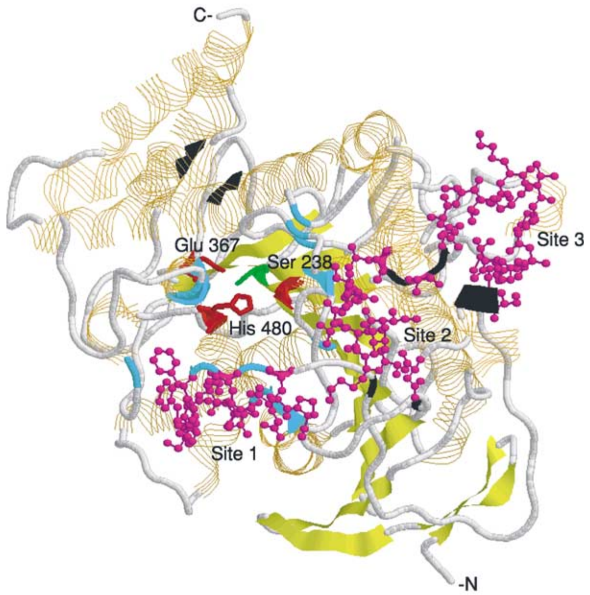

Figure 4 Three-dimensional cartoon structure of the carboxyl/cholinesterase domain of DmAChE (Harel *et al.*, 2000; PDB 1QO9; http://www.rcsb.org/pdb) generated by the RasMol program (http://www.openrasmol.org) looking down the catalytic gorge into the active site. Specifically indicated are residues contributing to the β-sheet (yellow; however, many are obscured behind the gorge and active site), several α-helices in the loops between β-strands (brown), six cysteines forming three disulfide bridges (black), the catalytic triad (Ser238, Glu367, His480, red) plus the candidate catalytic tetrad residue of Thomas *et al.* (1999) and Behra *et al.* (2002) (Ser264, green), 12 aromatic guidance residues lining the active site gorge (blue) and three peripheral substrate binding sites (purple). See also **Figure 6** for the relationship of these features to the primary sequence of the protein, and **Figure 5** for a schematic of the interior of the active site that cannot readily be shown in this figure.

and much of the external decoration for the structure. The structure is stabilized by three disulfide and four salt bridges.

There is quite detailed understanding of structure–function relationships in the regions of the AChE protein directly involved in catalysis. Many residues in these regions have been mutated *in vivo* in one or more of several cloned *ace* genes and the catalytic consequences for the protein determined (Doctor *et al.*, 1998; Ordentlich *et al.*, 1998; Villatte *et al.*, 2000a, 2000b; Boublik *et al.*, 2002; Pezzementi *et al.*, 2003 and references therein). **Figure 5** shows how the active site is built around the catalytic triad, with the nucleophilic serine protruding into the site on a conserved GXSXG pentapeptide termed the nucleophilic elbow. The rest of the site is largely composed of three subsites, which have variously been termed the leaving group pocket or P1 subsite (or in the particular case of AChE, anionic

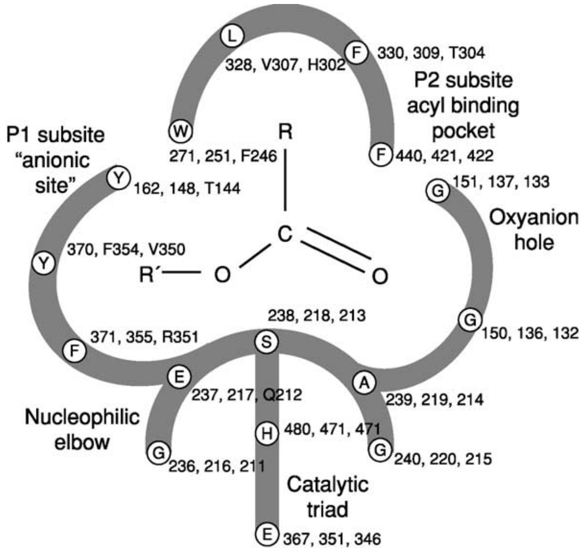

Figure 5 Schematic representation of the carboxyl/cholinesterase active site showing conserved amino acid residues. Each residue is shown with its single-letter code followed by its position in the sequences of DmAChE, LcαE7 (E3), and DmJHE, respectively. A letter is included where the residue in E3 or JHE differs from AChE. The residues of the catalytic triad, oxyanion hole, and nucleophilic elbow show strong conservation across active carboxyl/cholinesterases, while those constituting the subsites for the leaving and acyl groups of the substrate are more variable. These two subsites are described in greatest detail for AChE where they have often been called the P1 (or anionic) and P2 subsites, respectively. There is strong conservation of these sites across vertebrate and invertebrate AChEs (Harel *et al.*, 2000; Pezzementi *et al.*, 2003), but two of the indicated residues differ from AChE in E3 and seven of the eight differ in JHE.

site), the acyl pocket or P2 subsite, and oxyanion hole. These accommodate the alcohol, acid, and oxyanion moities of the substrate, respectively. Entry to the active site is via the catalytic gorge, which is over 20 Å long but only a few Å wide and is lined with several aromatic residues. Around the lip of the gorge are three "peripheral binding sites" which, when bound by substrate, trigger allosteric changes in the catalytic gorge that facilitate movement of substrate down the gorge. The end result is a particularly efficient enzyme with kinetics approaching diffusion limits (Taylor and Radic, 1994; Estrada-Mondaca and Fournier, 1998; Massoulie *et al.*, 1999).

Only two of the sequences in our phylogeny lack the additional serine (Ser264) which Thomas *et al.* (1999) and Behra *et al.* (2002) considered might, in combination with the established catalytic triad residues, form a "catalytic tetrad." One of these (33) is catalytically competent and the other (113) is not. Given its retention in so many catalytically inactive proteins, and its apparent absence in at least one catalytically competent enzyme, it seems likely to us that Ser264 has some highly conserved structural function in the active site, but not one directly involved in catalysis.

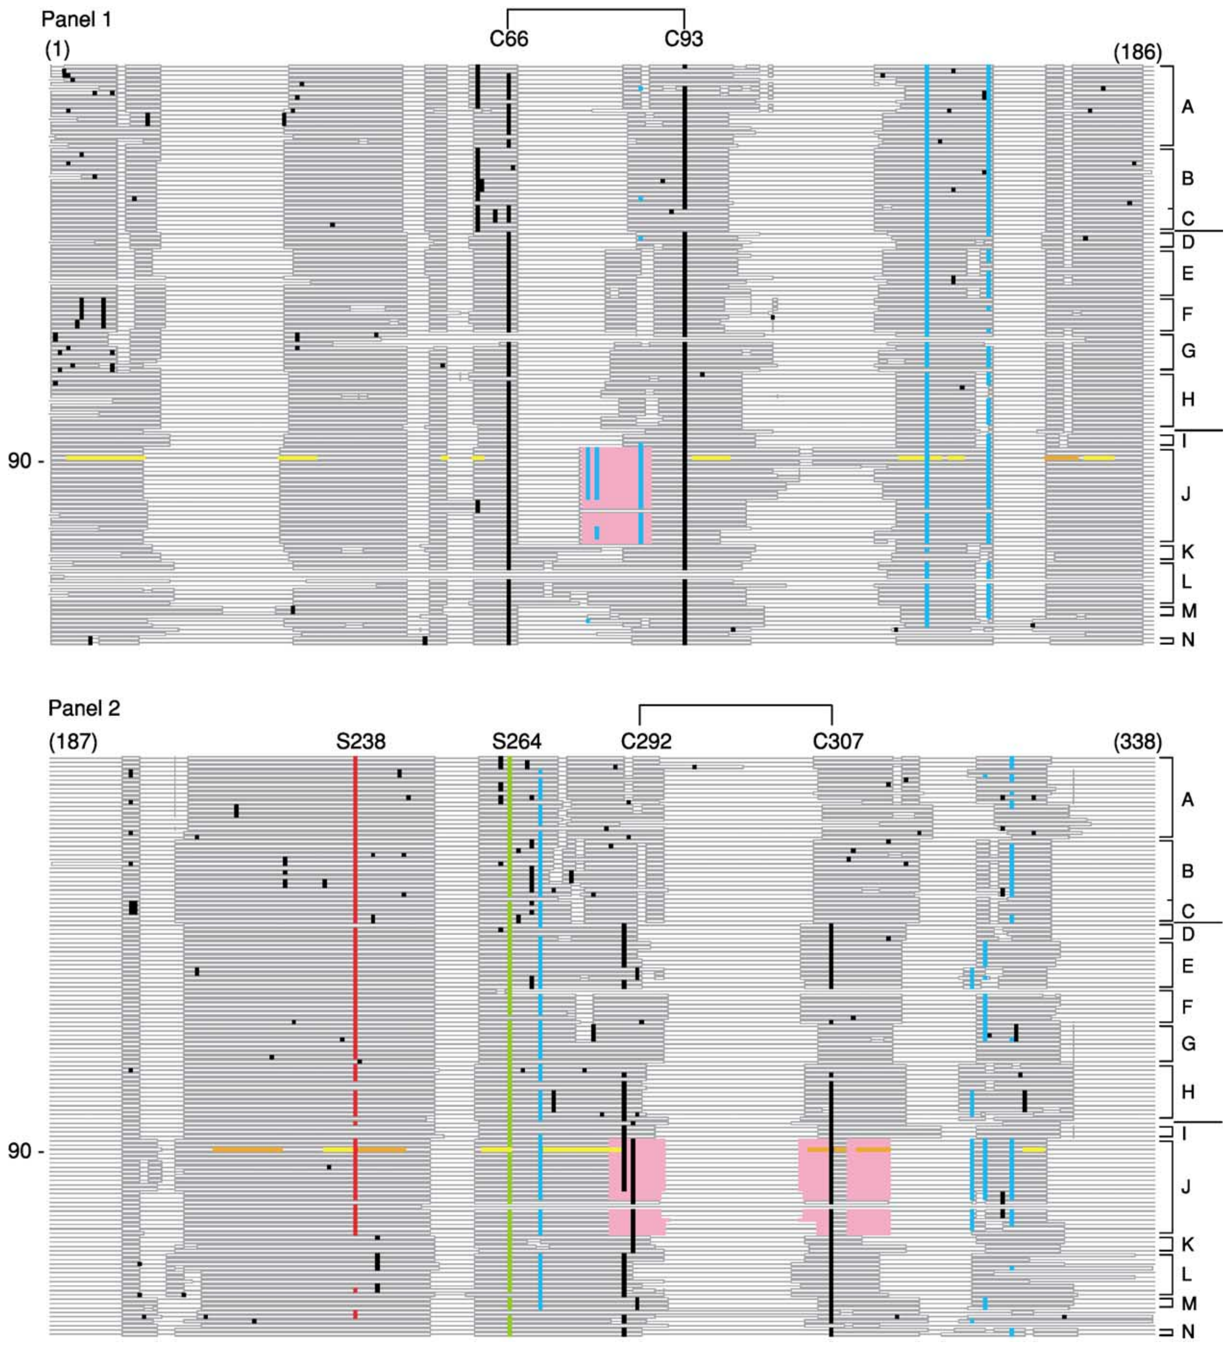

Figure 6 shows a qualitative alignment of the sequences in the phylogeny annotated with some of the major structural and/or functional motifs outlined above (a full alignment is available from the authors on request). In general terms, the alignment is consistent with the conservation of the overall arrangement of β-sheets and α-helices specifying the α/β hydrolase fold structure. Nevertheless there are also numerous clade-specific insertions/deletions, particularly in regions corresponding to loops towards the C-terminus of AChE. Many of these loops provide the external decoration to the core α/β hydrolase fold structure. Perhaps unsurprisingly some of the most distinctive arrangements occur in the noncatalytic clades. Importantly, however, the other catalytic clades also differ from AChE in aspects including two of the disulfide bridges, two of the peripheral substrate binding sites, and many of the aromatic gorge residues.

It is difficult to assess the significance of these differences in the absence of empirical structural information for any of the catalytic clades except AChE. However, they would seem to imply some major differences in the molecular mechanisms underpinning interactions with substrates. Modeling of a lepidopteran juvenile hormone esterase (JHE) indeed suggests at least two novel structural features of its active site that are instrumental to its particular catalytic capabilities (Thomas *et al.*, 1999) (see Section 5.10.4.2). There are also intriguing subclade-specific differences, for example, in the aromatic gorge residues of the hemipteran AChE-1 subclade, which may well have implications for catalysis, and the interactions with OP and carbamate insecticides (see Section 5.10.3.1). And, as discussed, the biochemistries of some of the insecticide resistance mutations imply major, allele-specific differences in aspects of structure affecting catalytic processes in certain catalytic carboxylesterases (see Sections 5.10.5.2, 5.10.6.1–5.10.6.3). It may be that a major reason for the proliferation of carboxyl/cholinesterases in higher eukaryotes is the functional diversity that can be achieved by relatively minor sequence changes in their catalytic machinery. Empirical structural data for some of the non-AChE catalytic clades would clearly now add greatly to our understanding of the functional diversity that has evolved among insect carboxyl/cholinesterases.

5.10.3. Acetylcholinesterase and Noncatalytic Neurodevelopmental Clades

The six major clades (I–N) containing insect sequences diverging earliest in the phylogeny (Figure 2) involve AChE and five clades of noncatalytic secreted proteins. The AChE is discussed first (see Section 5.10.3.1) because of the wealth of structure–function data available for it, followed by five noncatalytic clades (see Section 5.10.3.2).

Before doing so, however, it is worth noting some interesting parallels with the convergently evolved serine protease family of proteins in respect of the evolution of noncatalytic clades. Although they belong to a different structurally defined superfamily of proteins, the serine proteases generally use the same catalytic mechanism, built around the same catalytic triad and oxyanion hole, as the carboxyl/cholinesterases. (Indeed a few vertebrate esterases have been found in the serine protease family; see for example, Zschunke *et al.* (1991).) And, intriguingly, there are

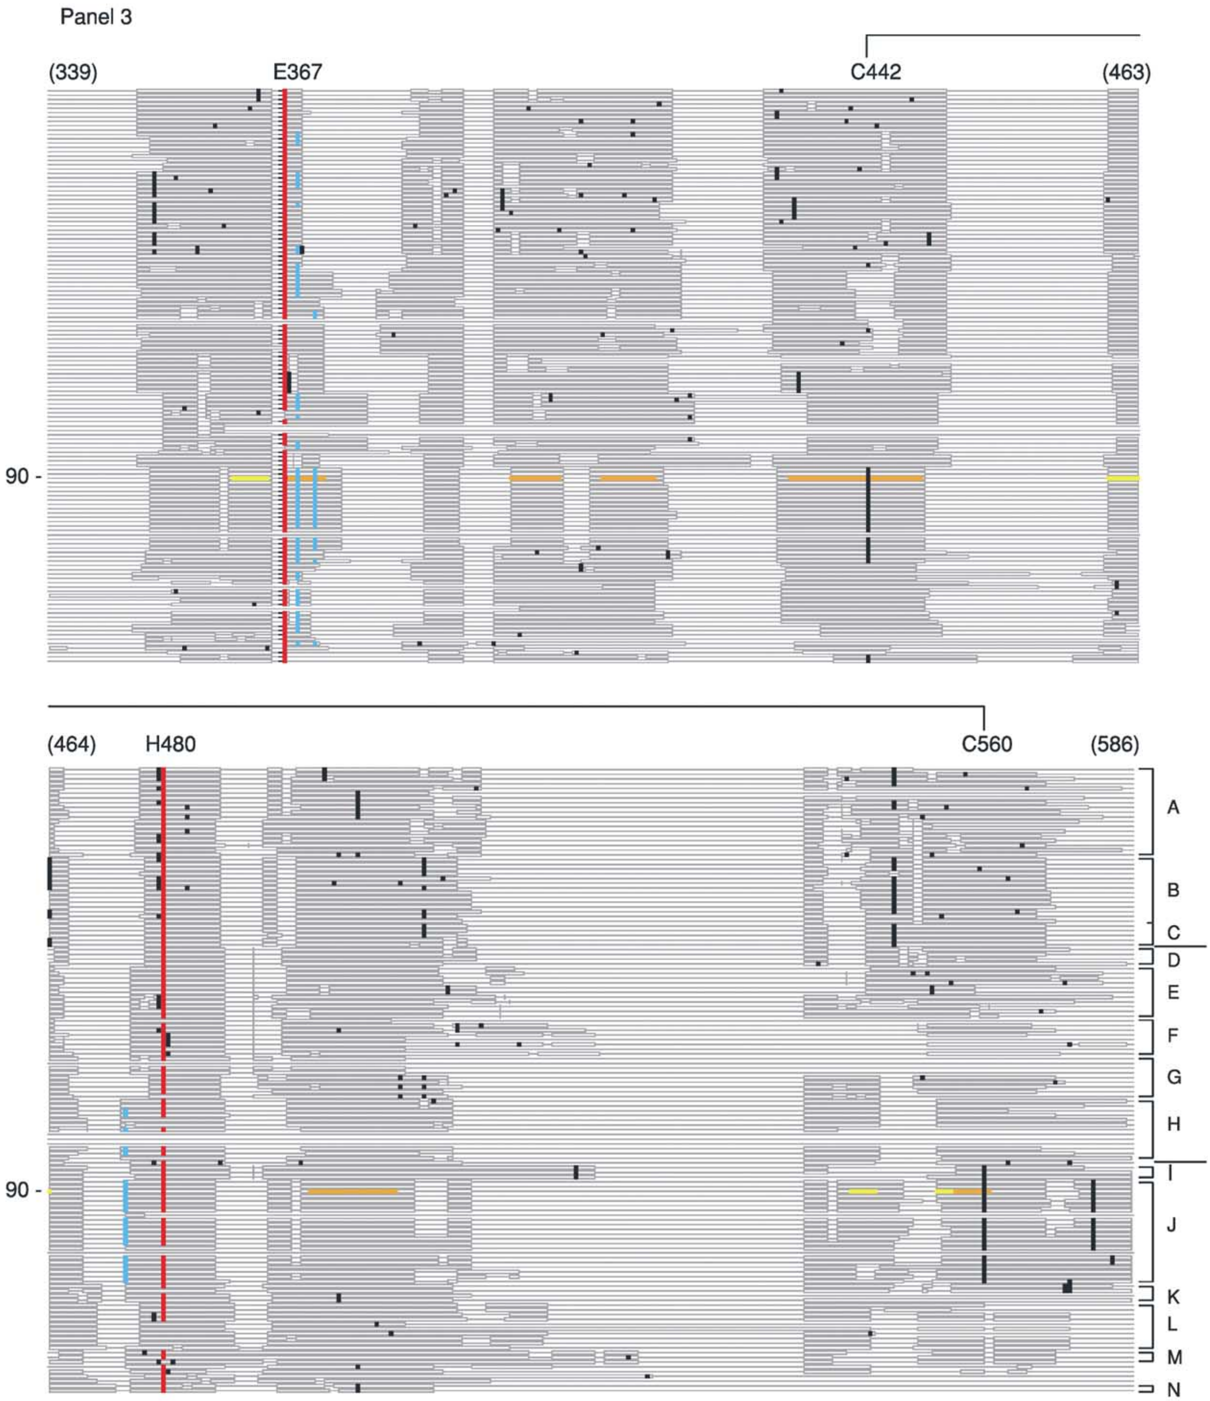

Figure 6 Block diagram generated by the GenDoc program (http://www.psc.edu) showing a qualitative alignment of the 132 carboxyl/cholinesterase amino acid sequences used to generate the phylogeny in **Figure 2**. Each sequence is simply represented as a series of blocks or lines to show the presence or absence of alignable residues. Sequences are ordered as in **Figure 2**, and their classification into the major clades recognized in **Figure 2** is shown on the right-hand side of each panel. The four panels cover sequences alignable to residues 1–186, 187–338, 339–463, and 464–585, respectively, in DmAChE (sequence 90 in the figure), which is used as a reference sequence because its tertiary structure is known (**Figure 4**). The β-strands and α-helices in DmAChE are shown in yellow and brown, respectively. Cysteines in all sequences are shown in black; those at residues 66 and 93, 292 and 307, and 442 and 560 in DmAChE are known to form three disulfide bonds. Aromatic residues corresponding to the aromatic gorge residues of DmAChE are shown in blue, conserved catalytic triad residues (Ser238, His480, and Glu367 in DmAChE) are shown in red, and the putative catalytic tetrad residue (Ser264 in DmAChE) of Thomas *et al.* (1999) and Behra *et al.* (2002) (which is present in all sequences covering the region except 33 and 113) in green. The known or presumptive peripheral substrate binding sites of all the AChE sequences are shown in pink. See **Figure 2** for the list of proteins lacking some amino or carboxy terminal sequence.

several lineages in the serine protease family, including in both vertebrates and invertebrates, that lack a consensus catalytic triad and are known to be catalytically incompetent. As with the carboxyl/cholinesterases, the ancestral state for the serine proteases, as seen in prokaryotes, is catalytic competence. However, early in the evolution of eukaryotes there was a proliferation of serine protease lineages with defective triads that took on ligand receptor roles in physiological processes ranging from neurodevelopmental regulation through to cellular immunity (Gabay and Almeida, 1993; Murugasu-Oei *et al*., 1995; Dimopoulos *et al*., 1997; Huang *et al*., 2000; Kwon *et al*., 2000; Kang *et al*., 2002). Many of these themes recur among the clades of noncatalytic carboxyl/cholinesterases.

5.10.3.1. Acetylcholinesterase

5.10.3.1.1. General biochemistry and genetics Although it also has other important roles, the major function of AChE is hydrolysis of the neurotransmitter acetylcholine after it has bound at cholinergic synapses. Hydrolysis is required to reset the synapses so that they can receive the next molecules of the neurotransmitter. Acetylcholine is an essential neurotransmitter in all higher eukaryotes but its role in insects is distinct from that in both vertebrates and nematodes. Accordingly insects also differ in their complement of *ace* genes and AChE proteins.

In vertebrates acetylcholine is an important neurotransmitter in both the central and peripheral nervous system and at neuromuscular junctions. Vertebrates only have one *ace* gene but, depending on the species, it can have three or four alternately spliced 3′ exons. This alternate splicing generates a range of variously oligomerized and soluble versus membrane-associated forms. The membrane-bound forms may be anchored with glycosyl phosphatidyl inositol (GPI) or complexed with collagen or the Type 1 transmembrane protein PRiMA (Massoulie *et al*., 1999; Perrier *et al*., 2002; Scholl and Scheiffele, 2003). The various forms are differentially expressed in the various cholinergic tissues above and in the blood and there are also some differences in their ontogenetic specificities. Vertebrates also have the closely related BuChE gene/enzyme system but this system is not directly involved in acetylcholine hydrolysis and it has no ortholog in nematodes or insects (Nicolet *et al*., 2003 and references therein).

Nematodes use acetylcholine as a neurotransmitter in both the central nervous system (CNS) and muscle tissue. *Caenorhabditis elegans* has four *ace* genes, but the products of two of these contribute the great majority of the organism's AChE activity (Massoulie *et al*., 1999, Combes *et al*., 2000, 2003). These two genes each encode a single transcript and class of product, one expressed as GPI-anchored dimers in neural tissue, and the other as a complex with collagen in muscle tissue and a small proportion of neurons. The form and function of the other two *ace* gene products are not well understood.

Insects use acetylcholine as a neurotransmitter in their CNS but their muscles largely use glutamate for this function. Accordingly their AChE is predominantly expressed as GPI-anchored dimers, with no equivalent of the collagen-complexed forms found in the muscles of vertebrates and nematodes (Massoulie *et al*., 1999). *Drosophila* and other higher Diptera (and possibly also a few lower Diptera) (Bourguet *et al*., 1998) only appear to have one *ace* gene but all other insects studied to date have two (Weill *et al*., 2002). Significantly, an acarine, the cattle tick *Boophilus microplus*, also has two (Baxter and Barker, 2002). In those arthropods with two *ace*/AChE gene/enzyme systems there appears to be just one system, *ace-1*/AChE-1 on the nomenclature of Weill *et al*. (2000, 2002, 2003) and Russell *et al*. (2004), which is responsible for neural acetylcholine hydrolysis, and it is also this one in which mutations conferring target site resistance to OP and carbamate insecticides may be found. The function of the other, *ace-2*/AChE-2, system is unknown; it is catalytically active but it is also speculated that it could have various cell–cell communication/adhesive properties, such as those described for *Drosophila* and vertebrate *ace*/AChE (Grisaru *et al*., 1999; Behra *et al*., 2002; Scholl and Scheiffele, 2003; Russell *et al*., 2004).

The currently available invertebrate AChE sequences form a strongly structured clade with four clearly discernable subclades in the phylogeny in **Figure 2**. One subclade, comprising solely the two inabundant *C. elegans* AChEs and its muscle/collagen-complexed AChE, is an outgroup to all the others. The next most distinct subclade includes the *C. elegans* AChE responsible for neural acetylcholine hydrolysis, plus the AChE-1 sequences of those insects and the tick which have two *ace* genes. The other two subclades are sister groups, one comprising the AChE-2s of the species with two *ace* genes, and the other comprising the AChEs of the higher Diptera. It follows that the single-*ace* genotype found in the higher Diptera has evolved by loss of the *ace-1* gene in an ancestor with a twin-*ace* genotype. And the intriguing corollary is that the originally noncholinergic AChE-2 in this ancestor has then reverted to a cholinergic role to cover for the loss of the AChE-1 (Weill *et al*., 2002; Russell *et al*., 2004).

The mature GPI-linked dimers that are the predominant form of AChE in *D. melanogaster* are produced through a complex set of posttranslational modifications of a primary 70 kDa translation product (Mutero and Fournier, 1992; Estrada-Mondaca and Fournier, 1998). This primary product comprises a 15 kDa N-terminal domain (in addition to a secretion signal), a ~55 kDa central carboxyl/cholinesterase domain, and a short C-terminal hydrophobic peptide. Dimerization occurs through an intermolecular disulfide linkage between homologous cysteine residues towards the C-terminal of the carboxyl/cholinesterase domain (Cys577) (**Figure 6**). The 15 and 55 kDa domains are proteolytically cleaved, albeit they remain noncovalently associated. Then the C-terminal hydrophobic peptide is replaced with the GPI anchor to the cell membrane. Several glycans are also added to the 15 and 55 kDa domains during processing.

At least four catalytically efficient AChE isoforms are clearly resolvable on native PAGE of *D. melanogaster* extracts (Fournier *et al.*, 1988, 1992; Zador, 1989; Healy *et al.*, 1991). The predominant one is the mature GPI-linked AChE dimer above (often also called the amphiphilic dimer). The others include amphiphilic monomers and hydrophilic dimers and monomers. The amphiphilic forms are largely localized to the CNS but the soluble, hydrophilic forms are not. It is unclear to what extent the alternate forms result from incomplete posttranslational processing as above, or are the result of the programmed deconstruction of the amphiphilic dimers. However, at least some contribution from both processes has been suggested. The amphiphilic dimers clearly have the major role in the cleavage of acetylcholine at synapses but it is also suggested that the other forms have other, as yet only poorly understood functions (Grisaru *et al.*, 1999). Notwithstanding their extra *ace* gene, insects in other orders still produce an essentially similar array of AChE isoforms (Toutant, 1989; Bourguet *et al.*, 1998).

Data for several species suggest that insect AChEs are generally, like their vertebrate counterparts, highly efficient kinetically (Gnagey *et al.*, 1987; Devonshire *et al.*, 1998; Chen *et al.*, 2001 and references therein). Specificity constants, k_{cat}/K_m, are of the order of $10^8\ M^{-1}\,s^{-1}$ for vertebrate AChEs with acetylcholine or (as more commonly measured) acetylthiocholine (Gibney *et al.*, 1990; Taylor and Radic, 1994). These values are the outcome of particularly high turnover rates (k_{cat} values approaching $10^4\ s^{-1}$) but only modest substrate affinities (K_m values approaching 50 μM). The latter are rationalized in terms of the likely high local concentrations of acetylcholine in the microenvironment of the synapse. Values for AChEs from the higher dipterans *D. melanogaster* and the Australian sheep blowfly *Lucilia cuprina* are three- to sixfold lower, due to slightly lower turnover values. Values for different isoforms of DmAChE are very similar to one another (Mutero and Fournier, 1992; Estrada-Mondaca and Fournier, 1998). There is one surprisingly low estimate of k_{cat} of around $2 \times 10^4\ min^{-1}$ for the Colorado potato beetle *Leptinotarsa decemlineata* (Zhu and Clark, 1995a) but the significance of this is unknown.

Two features of AChE biology in vertebrates that are generally associated with noncholinergic functions are also seen in insects, although evidence for the functional effects is still sparse for the insects (Darboux *et al.*, 1996; Scholl and Scheiffele, 2003). These features are the existence of nonneural soluble isoforms and the cell adhesive property. There are numerous studies showing effects of vertebrate AChE on the development of neuromuscular junctions and neurite outgrowth and many of these appear to depend on cell adhesive rather than catalytic properties of the enzyme (Sternfeld *et al.*, 1998; Grisaru *et al.*, 1999; Sharma *et al.*, 2001; Behra *et al.*, 2002, Scholl and Scheiffele, 2003). Soluble AChE is also overproduced in response to various stressors (Grisaru *et al.*, 1999; Lev-Lehman *et al.*, 2000). It is not known what parallels exist in insects but given the proliferation of closely related noncatalytic clades with clear functional effects they would seem well worth further investigation.

5.10.3.1.2. Target site insecticide resistance The activated or oxon forms of OP insecticides (see below) and carbamate insecticides act as essentially irreversible inhibitors, or suicide substrates, for AChE. This has proven true for all the well-characterized AChEs, although the insect AChEs seem particularly susceptible (Villatte *et al.*, 1998; Chen *et al.*, 2001; Boublik *et al.*, 2002). The inhibition occurs because the insecticides can serve as good substrates for the first step but poor substrates for the second step in the two-step reaction mechanism (**Figure 1**) (see Section 5.10.1.2). In other words they readily form a phosphorylated or carbamylated enzyme intermediate instead of the acyl-enzyme intermediate formed with carboxyl/choline ester substrates, but the phosphoryl- and carbamyl-enzyme intermediates are far more stable than the acyl-enzyme. The carbonyl carbon in the acyl enzyme intermediate is susceptible to nucleophilic attack by the oxygen of a water molecule, this oxygen being activated and oriented by residues in the active site. The slow to negligible hydrolysis of the

phosphoryl- and carbamyl-enzymes is presumably due to the inappropriate geometry of the phosphate group or an interfering effect of the nitrogen atom adjacent to the carbonyl carbon, respectively, that prevents hydrolysis by the enzyme's usual mechanism.

Inhibition as above for AChE probably occurs to varying degrees for all catalytically competent carboxyl/cholinesterases with OPs. To a lesser degree it may also occur for some of these other enzymes with some of the carbamates. Whatever their effects on the other carboxyl/cholinesterases, however, it is the consequences of the pesticides' inhibition of AChE on the functioning of cholinergic nerves that are assumed to underlie much of their insecticidal effect. Insects or acarines exposed to the insecticides can survive until a surprisingly high proportion of their AChE molecules are inhibited (Smissaert *et al*., 1975; Hoffmann *et al*., 1992; Devonshire *et al*., 2003), but above this threshold signal transduction down cholinergic nerves fails and paralysis occurs.

Well over 20 cases of target site resistance to OPs and/or carbamates have now been described in various insects and acarines (reviews: Fournier and Mutero, 1994; Bourguet *et al*., 1998; Devonshire *et al*., 1998; Russell *et al*., 2004). The cases cover most of the major orders of insect pests although hemipteran and dipteran cases predominate and there are relatively few lepidopteran examples (**Table 1**). There is a little evidence that upregulation of the amount of AChE can augment tolerance to the insecticides (Fournier *et al*., 1992; Charpentier *et al*., 1998) but high-level resistance seems only to be achieved by amino acid substitutions affecting the catalytic machinery of the enzyme that make it less sensitive to inhibition by the insecticides.

Russell *et al*. (2004) have discerned two major patterns of target site resistance to OPs and/or carbamates among many of the cases that have been most thoroughly characterized so far (**Table 1**). Each pattern is reported from several orders, and Pattern Two also from acarines, and there are examples of both from the genus *Culex*. Pattern One resistance is characterized at a bioassay level by much greater resistance to carbamates than to OPs and, at a biochemical level, by a much greater reduction in the sensitivity of AChE to the carbamates than to the OPs. The target site resistance reported in the mosquito *Culex pipiens*, the cotton aphid *Aphis gossypii*, and the peach potato aphid *Myzus persicae* are well-characterized examples of Pattern One resistance. Pattern Two resistance is characterized by more equivalent levels of resistance and/or reductions in AChE sensitivity to the two classes of insecticide. Some well-characterized examples of Pattern Two resistance involve the mosquito *Culex tritaeniorhynchus*, *D. melanogaster*, the housefly *Musca domestica*, the olive fruit fly *Bactrocera oleae*, and the silverleaf whitefly *Bemisia tabaci*. Importantly, the two types of pattern as defined by the bioassay and biochemical criteria also correspond to different sets of mutation in the catalytic machinery of AChE.

Molecular data on the resistance mutations are now available for 10 species in **Table 1**. A total of 18 mutations have been confidently associated with resistance in eight of the species, with four polymorphisms tentatively associated with resistance in the beetle *L. decemlineata* and the two-spotted spider mite *Tetranychus urticae*. Except for the *L. decemlineata* data, all cases involve the cholinergic form of AChE. As many as five mutations have been reported in each of *D. melanogaster* and *M. domestica*. However, the 22 differences involve just 11 DmAChE-equivalent sites. Mutations at five of the sites occur more than once in the data, sometimes involving the same substitutions in different species. Ten of the 11 sites lie in or near the active site/gorge.

At least on the current data, the options for Pattern One resistance mutations seem more constrained than those for Pattern Two resistance. A G151S mutation (on DmAChE numbering, which is used throughout this section) in the oxyanion hole has been associated with one clear case of Pattern One resistance, in *C. pipiens*, as well as two other anopheline cases almost certainly also of this pattern, in *Anopheles gambiae* and *A. albimanus* (Weill *et al*., 2002, 2003, 2004). It is unclear as yet how this relatively conservative mutation in the three lower dipterans reduces the sensitivity of the active site to inhibition by carbamates in particular. However, it is intriguing that a different mutation, to an aspartate, at the equivalent oxyanion hole residue of certain *L. cuprina* and *M. domestica* carboxylesterases actually confers metabolic resistance to OPs by allowing those enzymes to complete the second step of the reaction with OP substrates, albeit at the expense of their carboxylesterase activity (see Section 5.10.5.2).

However, Pattern One resistance in the hemipteran *M. persicae* is associated not with G151S but with a S371F change (Nabeshima *et al*., 2003). S371 is also close to the catalytic residues at the base of the gorge and has been implicated in substrate guidance and binding. While this is considered to be primarily with the alcohol portion of a carboxyl ester, its location (not obvious from the two-dimensional cartoon in **Figure 5**) is on the boundary between the anionic and acyl binding sites where it can also affect binding of the alkoxy group of OPs (Ordentlich *et al*., 1993, 1996; Millard *et al*.,

Table 1 Summary of cases of resistance to OPs and/or carbamates resulting from an insensitive AChE in various insect species; cases are included on the basis of bioassay and/or biochemical data implicating an insensitive AChE and, where possible, classified according to the two patterns of AChE insensitivity identified by Russell *et al.* (2004)[a]

Species	*Resistance profile*	*Resistance mutations*[b]	*Reference*
Pattern One: Carbamate resistance > OP resistance			
Thysanoptera			
Scirtothrips citri (citrus thrip)	AChE insensitivity is greater for propoxur than paraoxon in a resistant strain		Ferrari *et al.* (1993)
Hemiptera			
Aphis gossypii (cotton aphid)	Carbamate resistance (pirimicarb) is much greater than OP resistance (demeton-*S*-methyl, methamidiphos, monocrotophos, omethoate, pirimiphos-methyl)		Moores *et al.* (1996), Menozzi, cited in Weill *et al.* (2002), Li and Han (2002)
Myzus persicae (peach potato aphid)	Marked AChE insensitivity to pirimicarb (>100×) but no insensitivity to a range of other carbamates (e.g., methomyl, carbofuran, aldicarb, ethiofencarb) or OPs (demeton-*S*-methyl, dichlorvos, paraoxon)	S371F (gorge guidance residue near triad His/acyl pocket)	Moores *et al.* (1994), Williamson *et al.*, cited in Villatte and Bachmann (2002); Nabeshima *et al.* (2003)
Nephotettix cincticeps of Iwata and Hama (green rice leafhopper)	43-fold resistance to propoxur, 43-fold to carbaryl, 6-fold to malathion, 18-fold to malaoxon		Iwata and Hama (1972)
Coleoptera			
Leptinotarsa decemlineata of Wierenga and Hollingworth (Colorado potato beetle)	>550-fold resistance to carbofuran and 9-fold resistance to azinphosmethyl		Wierenga and Hollingworth (1993)
Lepidoptera			
Helicoverpa armigera (cotton bollworm)	35-fold resistance to thiodicarb, 75-fold to methomyl and no cross-resistance to OPs		Gunning *et al.* (1996a)
Heliothis virescens (tobacco budworm)	k_i values for AChE inhibition are 10- to 100-fold less for propoxur than for several OPs		Brown and Bryson (1992)
Lower Diptera			
Anopheles albimanus of various authors	k_i values are 100-fold less for propoxur than paraoxon		Ayad and Georghiou (1975)
	k_i values are ~10-fold less for propoxur than for malaoxon		Hemingway *et al.* (1985)
	Resistance levels are >1000-fold for propoxur, 73-fold for carbaryl and 1.2–38-fold for OPs		Hemingway and Georghiou (1983)
Culex pipiens complex (house mosquito)	k_i values for three strains are 1000-fold less for propoxur than malaoxon, paraoxon, and aldicarb; resistance factors for one strain are 1600-fold for propoxur, 18-fold for chlorpyriphos, 140-fold for malaoxon and 5-fold for temephos	G151S (oxyanion hole) in all strains	Weill *et al.* (2002, 2003, 2004)
Pattern Two: Carbamate resistance ~ OP resistance			
Hemiptera			
Bemisia tabaci (silverleaf whitefly)	Similar k_i values for OPs and carbamates		Byrne and Devonshire (1993, 1997)
Coleoptera			
Diabrotica virgifera (western corn rootworm)	Slight increase in AChE insensitivity to paraoxon in a strain resistant to a range of OPs and carbaryl		Miota *et al.* (1998)
Lepidoptera			
Spodoptera frugiperda (fall armyworm)	Similar k_i values for OPs and carbamates		Yu (1991)

Continued

Table 1 Continued

Species	*Resistance profile*	*Resistance mutations*[b]	*Reference*
Lower Diptera			
Culex tritaeniorhynchus	AChE from a resistant strain has 870-fold decrease in OP sensitivity, and to a lesser extent to carbamates	F371W (gorge guidance residue near triad His/acyl pocket)	Nabeshima *et al.* (2004)
Higher Diptera			
Bactrocera oleae (olive fruit fly)	k_i data indicate insensitivity to omethoate and paraoxon, but not to propoxur	G436S (near triad Glu) I161V (gorge guidance residue near anionic site)	Vontas *et al.* (2001, 2002)
Drosophila melanogaster (vinegar fly)	Similar levels of resistance to OPs (paraoxon, malaoxon) and carbamates (carbaryl, propoxur)	F77S (anionic site) I161V/T (gorge guidance residue near anionic site) G265A (near triad Ser) F330Y (acyl pocket)	Mutero *et al.* (1994)
Musca domestica of Walsh *et al.* (housefly)	Similar k_i values for OPs and carbamates	V182L (little effect) G265A/V (near triad Ser) F330Y (acyl pocket) G368A (near triad Glu)	Walsh *et al.* (2001)
Acarina			
Amblyseius potentillae (predatory mite)	Similar k_i values for paraoxon and propoxur		Anber and Overmeer (1988)
Tetranychus kanzawai (Kanzawa spider mite)	OP resistant strains with low cross-resistance to carbamates		Kuwahara (1982)
Unknown			
Thysanoptera			
Frankliniella occidentalis (western flower thrip)	Ten-fold decrease in AChE sensitivity to diazoxon inhibition in a resistant strain		Zhao *et al.* (1994)
Homoptera			
Cacopsylla pyri (European pear sucker)	Resistance to monocrotophos and 70-fold decrease in k_i for monocrotophos		Berrada *et al.* (1994)
Hemiptera			
Lygus hesperus (plant bug)	34-fold decrease in AChE sensitivity to paraoxon inhibition in a resistant strain		Zhu and Brindley (1990a)
Nephotettix cincticeps of Tomita *et al.*	AChE inhibition by propoxur		Tomita *et al.* (2000)
Coleoptera			
Leptinotarsa decemlineata	Resistance to azinphosmethyl	S276G (peripheral binding site/active site)[c]	Zhu and Clark (1995a, 1995b), Zhu *et al.* (1996)
Lower Diptera			
Anopheles albimanus of Weill *et al.*	Resistance to carbamates and OPs based on AChE insensitivity but details not reported	G151S (oxyanion hole)	Weill *et al.* (2004)
Anopheles gambiae (African malaria mosquito)	Resistance to carbosulfan	G151S (oxyanion hole)	N'guessan *et al.* (2003); Weill *et al.* (2003, 2004)
Higher Diptera			
Musca domestica of Kozaki *et al.*	>40-fold decrease in AChE sensitivity to fenitroxon in resistant individuals	G265A (near triad Ser) F330Y (acyl pocket)	Kozaki *et al.* (2001)
Acarina			
Boophilus microplus (southern cattle tick)	Resistance to OPs		Baxter and Barker (2002)
Tetranychus urticae (two-spotted spider mite)	Multi-resistant strain has AChE that is more sensitive to OPs and carbamates (not less)	S/G151S (oxyanion hole) F371F/C (gorge guidance residue near triad His/ acyl pocket) D/E160E (vicinity of gorge)	Anazawa *et al.* (2003)

1999). The clear inference from the *M. persicae* data is that it can also have profound effects on the binding of certain carbamates, at least in this hemipteran version of AChE-1.

In fact it is suspected that this *M. persicae* case may represent a subtype of Pattern One resistance that is specific for dimethyl carbamates like pirimicarb and the dimethyl carbamoyltriazole triazamate, and notably not including resistance to monomethyl carbamates such as propoxur that have been used to diagnose many of the mosquito and some of the other cases of Pattern One resistance above. Interestingly, the S371F change brings the *M. persicae* sequence into line with the status of this residue as a strongly conserved phenylalanine in most carboxyl/cholinesterases. Whatever benefit the serine might otherwise confer on susceptible aphids, it seems that it allows an accommodation of the slightly bulkier dimethyl carbamates at the base of the gorge that is hindered by the larger phenylalanine more usually found at this position in carboxyl/cholinesterases.

Another hemipteran, *A. gossypii*, also shows high resistance to pirimicarb, without cross-resistance to monomethyl carbamates, so it will be interesting to see if the same mutation occurs in its AChE-1. If so, it might suggest that the potency of the dimethyl carbamates as aphicides could at least in part be due to the unusual status of AChE-1 residue 371 in (susceptible) aphids. Interestingly, two other mutations to different residues which give very different resistance profiles have also been reported at residue 371 outside the Hemiptera and are discussed below.

A total of 12 mutations have been reported in three higher dipteran cases of known or presumptive Pattern Two resistance, involving *D. melanogaster*, *M. domestica*, and *B. oleae* (Mutero *et al.*, 1994; Kozaki *et al.*, 2001; Vontas *et al.*, 2001, 2002; Walsh *et al.*, 2001). These occur in just seven DmAChE-equivalent sites, with three of these sites (161, 265, 330) each used in two or three of the mutations. One of the 12 mutations, V182L, is located at some distance from the catalytic residues and apparently makes little contribution to resistance. However, the other 11 mutations all involve six sites at the base of the gorge, and most are substitutions to larger residues, which modeling suggests could act by constricting the space at the base of the gorge in such a way as to reduce the insecticides' access to the catalytic residues. Why they should effect Pattern Two as opposed to Pattern One resistance is as yet unclear.

Elegant kinetic analyses of AChE variants with different combinations of most of the 11 mutations indicate that most of them individually contribute towards the insensitivity phenotype. This is significant because various alleles in natural populations only contain a subset of the substitutions. Introduction of some of the same changes into the AChEs of *Aedes aegypti* and *L. cuprina* has a similar effect on the inhibition kinetics of baculovirus-expressed enzyme (Vaughan *et al.*, 1997b; ffrench-Constant *et al.*, 1998; Chen *et al.*, 2001); this supports the view that these or very similar mutations could underlie other cases of Pattern Two resistance.

Pattern Two resistance in *C. tritaeniorhynchus* involves a single change, F371W, not seen elsewhere as yet in this pattern (Nabeshima *et al.*, 2004). However, it does involve the same site at which other mutations have been associated with Pattern One resistance in *M. persicae* (above) and another very different resistance in the mite *T. urticae* (below). It fits the trend of changes to bulkier side chains evident in many of the mutations in both patterns. The fact that quite different insensitivity and resistance profiles can be obtained by the various substitutions at this site seen in different species may be an indication that the precise location of this residue around the boundary of the acyl and anionic sites differs among the AChEs of these species.

Russell *et al.* (2004) could not assign the case of target site resistance to azinphosmethyl in the beetle *L. decemlineata* to a pattern in the absence of toxicological or biochemical data on carbamate

[a]Cases were assigned to Pattern One or Two where bioassay and/or biochemical data were available for both OPs and carbamates. Pattern One resistance involves greater (target site) resistance factors and/or greater reductions in AChE sensitivity to carbamates than OPs. Pattern Two resistance involves more similar, or greater (target site) resistance or reductions in AChE sensitivity for the OPs compared to the carbamates. Cases for which an insensitive AChE has been reported, but for which the resistance profiles for both OPs and carbamates have not been reported, are classified as ''unknown.''

[b]All identified mutations except the S276G reported in *L. decemlineata* by Zhu *et al.* (1996) are in the cholinergic AChE, i.e., AChE in the higher Diptera and AChE-1 elsewhere (on the nomenclature of Weill *et al.* (2000), 2002, 2003 and Russell *et al.* (2004)). Residues are numbered according to the nomenclature for DmAChE (Harel *et al.*, 2000) with the residues in susceptible strains given before the numbers and those in resistant strains after them. A dash indicates that the mutation has yet to be identified. Bracketed comments on locations are taken from the authors or extrapolated from Harel *et al.* (2000).

[c]Weill *et al.* (2002) suggest that the association with resistance is not significant.

sensitivity. More importantly, Weill *et al.* (2003) have also expressed doubts about the significance of the resistance phenotype. This is important because molecular data (Zhu *et al.*, 1996) implicate an S276G change in the presumptively noncholinergic AChE-2 (Weill *et al.* (2003) and Russell *et al.* (2004) nomenclature) in this resistance. Neither this residue, nor this form of AChE have previously been implicated in resistance but modeling also puts the change in the vicinity of the active site, albeit not as close to the catalytic residues as most of those above. Zhu *et al.* (1996) suggest that the substitution could affect interactions with the pesticide either at the peripheral binding site or within the gorge. Clearly, further work is required to elucidate the biochemistry and molecular genetics of AChE-based resistance in this species.

The case of *T. urticae* is remarkable in that it apparently involves change(s) to AChE-1 that make it more, not less sensitive to inhibition by OPs and carbamates. No fixed differences have yet been reported in AChE-1 between susceptible and resistant strains. However, Anazawa *et al.* (2003) found that residue 151 in the oxyanion hole was polymorphic for Ser and Gly in susceptible strains but only Ser in resistant strains, residue 371 at the base of the gorge was polymorphic for Phe and Cys in resistant strains but only Phe in susceptibles, and residue 160, also near the active site, was polymorphic for Asp and Glu in susceptibles and only Glu in resistance. Residue 160 has not been implicated in resistance previously but both the other two have been. In both cases the precedent data (G151S, S371F, and F371W) associate changes to bulkier residues at these sites with reduced AChE sensitivity and target site resistance. In *T. urticae*, the F371F/C polymorphism associates a bulkier residue with lower AChE sensitivity but target site susceptibility, while the reverse is true for S/G151S. Whilst clearly difficult to interpret in detail, at face value the *T. urticae* results would seem to imply a very different AChE (in)sensitivity mechanism which nevertheless involves changes to some of the same residues implicated in the other AChE-based target site resistances so far resolved at a molecular level.

Some important insights into AChE-based target site resistance have also been gained from detailed analyses of the inhibition kinetics of various synthetic mutants of DmAChE. A series of studies (Villatte *et al.*, 1998, 2000a, 2000b; Boublik *et al.*, 2002) have examined a large number of substitutions at some of the sites recurrently implicated in natural resistance, as well as selected changes at over 20 other sites in the active site/gorge. DmAChE is already more sensitive than most characterized noninsect AChEs to inhibition by OPs and carbamates (as indeed are other well-characterized insect AChEs) (Chen *et al.*, 2001) but a small number of mutations were found to make it even more sensitive. Most changes, however, decreased sensitivity, and most also reduced acetylcholine hydrolytic activity, although many still allowed levels of acetylcholine hydrolysis predicted to be viable *in vivo*. Some changes had generally greater effect on the interactions with OPs than with carbamates, others had more impact on carbamate interactions, and some had large effects on both. There was also significant, mutation-specific variation both among OPs and among carbamates in the size of the effects. Some mutations masked the effects of others. Several mutations at sites like I161 and F371 where natural resistance has been reported were found to have large effects, but several sites closer to the lip of the gorge and the peripheral binding sites were also found to cause significant sensitivity changes. Overall the results suggest that there may be several more options for Patterns One or Two resistance, or indeed other classes of target site resistance mutations, than have been documented thus far, with the “choice” among options depending both on the particular pesticides involved and on genetic constraints like pre-existing codon usage and variability at the key sites.

It will also not be surprising if there are phylogenetic differences in the mutations underlying the various insensitivity phenotypes. There are already indications of this in the data to date. For example, the three lower dipteran cases of known or presumptive Pattern One resistance all involve a G151S change, whereas, in *M. persicae* the causative change appears to be S371F. Likewise, none of the several changes seen in the three higher dipteran cases of Pattern Two is the same as the one found underlying this pattern in *C. tritaeniorhynchus*. It is suspected that such differences reflect phylogenetic differences in the details of the geometry and composition of the gorge; significant structural differences are indeed suggested by the alignment in **Figure 6**, the hemipteran AChE-1 subclade being but one example. The differences between the higher Diptera and other lineages reflecting their use of nonorthologous AChEs for cholinergic functions are also expected.

Both Pattern One and Pattern Two resistances seem to compromise the kinetics of acetylcholine hydrolysis to some degree (Fournier and Mutero, 1994; Devonshire *et al.*, 1998), which can lead to a fitness cost for resistant genotypes in the absence of the insecticide (Roush and McKenzie, 1987). The costs have been most thoroughly explored in two cases of Pattern One resistance.

The insensitive AChE in *M. persicae* affects fitness in two ways (Foster *et al*., 2003). Aphids with the modified AChE reproduce more slowly and are more responsive to alarm pheromone. These effects have only recently been discerned as they are usually superimposed on fitness costs due to other resistance factors in clonal lines of this species (see Section 5.10.4.3.2). How they are mediated in terms of the physiology of AChE is as yet unclear.

A severe fitness cost has been described for the Pattern One resistance in *C. pipiens*; estimates by various means have put the fitness cost as high as about 60% (Chevillon *et al*., 1997; Lenormand *et al*., 1999). As a consequence there has been clinal variation in resistant allele frequencies away from geographic areas with heavy use of the insecticides towards those with much lighter use. There has also been regular seasonal variation in the frequency of the resistant allele in localities only seasonally exposed to the insecticide. Most recently a duplication of the *ace-1* locus has arisen and swept to high frequency in *C. pipiens* that combines both the susceptible wild-type and the resistant allele (Lenormand *et al*., 1998a). This combination apparently provides both sufficient resistant AChE-1 protein to ensure survival in the presence of the insecticide, and sufficient wild-type AChE-1 protein to restore near-wild-type neurotransmission in the absence of the insecticide.

5.10.3.2. Noncatalytic Clades

The five clades of noncatalytic proteins considered here comprise the neurotactins (clade N in **Figure 2**), which constitute an outgroup to all the others, and then the gliotactins (M), putative neuroligins (L), and two functionally anonymous radiations (I, K) which are all more closely related to the AChEs (J). expectThe greater phylogenetic separation of the neurotactins is also borne out by other aspects of their biology. For example, the neurotactins have an N-terminal extension which specifies transmembrane and intracellular domains, whereas all the others appear to specify these domains in C-terminal extensions (Grisaru *et al*., 1999). Nevertheless, as shown, there are some striking biochemical similarities between the neurotactins, gliotactins and AChE, and these are specified by their shared carboxyl/cholinesterase domains.

Drosophila melanogaster and *A. gambiae* each have a single neurotactin. In *D. melanogaster* it is only reported as a transmembrane glycoprotein in neuronal and epithelial tissue of embryos and larvae (Fremion *et al*., 2000). It does not have a consensus N-terminal secretion signal, presumably relying on a nonconventional signal or another mechanism, such as translocation following membrane insertion (see Section 5.10.2.2). Its ligand is a secreted protein, Amalgam, which is a member of the immunoglobulin superfamily (Liebl *et al*., 2003). However, there is as yet no evidence for a role in immunity in *Drosophila*. Instead, the Amalgam–neurotactin complex, aggregated with other as yet only partly ascertained proteins, acts as a heterophilic cell adhesion system in axon guidance processes during development (Hortsch *et al*., 1990; Speicher *et al*., 1998). Notably, the adhesive properties of neurotactin in *in vitro* systems can be mirrored by chimeric neurotactin proteins in which its carboxyl/cholinesterase domain is replaced with homologous sequences from the AChEs of *D. melanogaster* or the eel *Torpedo marmorata*, or *D. melanogaster* glutactin (Darboux *et al*., 1996) (see Section 5.10.4.1). *Inter alia*, this bears out the evidence for the cell adhesive capabilities of the AChEs (see Section 5.10.3.1.2).

Significantly, both the Amalgam-binding and cell adhesive functions of *D. melanogaster* neurotactin have been mapped to a segment of about 140 residues corresponding to the N-terminal region of the carboxyl/cholinesterase domain of AChE (in fact most of panel 1 in **Figure 6**) (Darboux *et al*., 1996; Fremion *et al*., 2000). Botti *et al*. (1998) have also shown strong conservation of surface charge around the lip of the gorge among AChE, neurotactin, and some of the other noncatalytics. All this suggests that N-terminal regions in the noncatalytics corresponding to some of the peripheral substrate binding machinery and parts of the gorge in AChE are responsible for their ligand binding functions.

There is no known vertebrate ortholog of insect neurotactin (although unfortunately there is an unrelated vertebrate peptide which is also called neurotactin) (Jung *et al*., 2000). There is another inactive carboxyl/cholinesterase in vertebrates, thyroglobulin, which is quite similar to insect neurotactin in its carboxyl/cholinesterase domain and which is also like insect neurotactin, and unlike the other noncatalytics has a membrane-spanning domain as an N-terminal extension (Grisaru *et al*., 1999; Scholl and Scheifele, 2003). However, thyroglobulin apparently functions in thyroid hormone delivery which clearly has no close parallel with insect neurotactin.

Although there are no functional data on the putative insect neuroligins, as a group they show clear sequence orthology with the well-studied vertebrate neuroligins and they have therefore been tentatively identified as such (Ranson *et al*., 2002). There are four neuroligin genes in the vertebrates studied to date, and these all express an array

of alternately spliced transcripts, generating further diversity at the protein level (Bolliger *et al*., 2001). Even greater diversity is seen in their ligands, the neurexins, which exist in hundreds of forms (Tabuchi and Sudhof, 2002). Neurexin diversity is again generated from about three genes, with alternate promoters and downstream splice variants generating the diversity. The well-studied neuroligin-1 group are postsynaptic membrane proteins that trigger synapse formation around axon contacts (Song *et al*., 1999; Clarris *et al*., 2002). Their extracellular carboxyl/cholinesterase domains attract and aggregate a subset of neurexins and certain other proteins, and their cytoplasmic domains then respond by assembling part of the exocytotic apparatus for the synapse (Dean *et al*., 2003). It is assumed that the diversity of neuroligins and neurexins gives specificity in the formation and organization of the synapses (Ichtchenko *et al*., 1996). There is some evidence for direct functional interactions between certain neuroligin-1 proteins and AChE in promoting neurite development (Grifman *et al*., 1998; Grisaru *et al*., 1999). At least in part this involves a level of functional overlap but how this is mediated in terms of ligands and specific sequence/structural motifs is unknown.

The insect neuroligin clade currently contains four pairs of *D. melanogaster* and *A. gambiae* orthologs, plus one additional *A. gambiae* sequence. EST and bioinformatic analyses also suggest at least some use of alternate splicing to generate additional diversity of gene products (Claudianos, unpublished data). Interestingly *D. melanogaster* only has one neurexin gene although, again, it apparently encodes at least a small number of different neurexin protein isoforms (Tabuchi and Sudhof, 2002; Schulte *et al*., 2003). Nevertheless it seems unlikely that the insect neuroligin/neurexin system involves the same scale of protein diversity as seen in their vertebrate orthologs, so there has probably been significant divergence in their function(s).

There are just a single *D. melanogaster* sequence and its *A. gambiae* ortholog in the insect gliotactin clade at this point. The *D. melanogaster* gliotactin is a transiently expressed transmembrane protein in the peripheral nervous system of the developing embryo, where it is an essential component of a paracellular structure called the septate junction (Genova and Fehon, 2003). The *A. gambiae* sequence has a conventional N-terminal secretion signal but the *D. melanogaster* sequence does not; like neurotactin above, it may use a nonconsensus secretion signal or a membrane insertion–translocation mechanism for extracellular presentation. Gliotactin acts in part as a transmembrane anchor for the septate junction structure, which also contains a small number of other proteins, notably including neurexin. There is no direct evidence that the neurexin acts as a ligand for the gliotactin although it might not be surprising, given the vertebrate data above indicating that neurexins are ligands for the related neuroligin receptors. There is evidence that the insect gliotactin and the septate junction function in part in axon guidance during development (Schulte *et al*., 2003). However, the major role of the complex appears to be maintenance of the transepithelial nerve–hemolymph permeability barrier. In mutant embryos with defective gliotactin the integrity of this barrier is broken down, the peripheral motor axons are exposed to high concentrations of potassium ions from the hemolymph, action potentials therefore do not propagate, and substantive paralysis results (Auld *et al*., 1995).

Consistent with the colocalization with neurexin in the septate junction, there are suggestions in the literature that *D. melanogaster* gliotactin is equivalent to the neuroligin-3 subset of vertebrate neuroligins, which are also found in ensheathing glia (Gilbert *et al*., 2001). However, this correspondence does not reflect genuine orthology at a sequence level (Claudianos, unpublished data) suggesting either a functional shift or functional overlap between the two receptor radiations.

One of the two functionally anonymous noncatalytic clades (K in **Figure 2**), comprising just two pairs of *D. melanogaster* and *A. gambiae* orthologs, is phylogenetically closely related to the neuroligins and conceivably could represent additional members of this neurexin binding functional group. Like the neuroligins, their sequences show C-terminal extensions beyond their carboxyl/cholinesterase domains with clear consensus transmembrane domains and downstream, presumptively cytoplasmic, domains. The other functionally anonymous noncatalytic clade (I in **Figure 2**) includes a single orthologous sequence from each of *D. melanogaster*, *A. gambiae*, and *A. aegypti*. It is less closely related to the neuroligins, or AChEs. Although it does have a C-terminal extension it does not contain any good match with consensus membrane-spanning motifs. Functional analysis of both these clades using all the tools of modern *Drosophila* genetics would seem to be highly worthwhile from here.

5.10.4. Secreted Catalytic Clades

There are five major clades of secreted, generally catalytically active carboxyl/cholinesterases (**Figure 2**). One contains the CNS adhesive protein glutactin and its relatives, most apparently catalytically active

(clade H) (see Section 5.10.4.1). Two others contain JHEs and similar enzymes albeit, interestingly, these two clades are not simply sister groups (clades F, G) (see Section 5.10.4.2). The fourth contains the well-studied dipteran β-esterases and their hemipteran relatives implicated in insecticide resistance (clade E) (see Section 5.10.4.3). Little is known about the fifth clade but it does include one enzyme putatively identified as a pheromone esterase (clade D) (see Section 5.10.4.4).

5.10.4.1. Glutactin and Related Proteins

This clade currently only contains *D. melanogaster* and *A. gambiae* sequences, four for the former and nine for the latter, which are arranged in two chromosomal clusters in each species. The only member of the clade for which there is currently functional information is *D. melanogaster* glutactin, which is an outgroup to all the others. This protein is catalytically inactive, as are two of the other *D. melanogaster* sequences. Conversely, the duplicate of *D. melanogaster* glutactin (82 in **Figure 2**) and all the *A. gambiae* sequences have consensus catalytic triads, and so are potentially catalytically competent. Glutactin is also one of only two proteins in this clade known to have additional carboxy terminal sequence specifying transmembrane and cytoplasmic domains, the other being another of the catalytically incompetent *D. melanogaster* proteins (76).

Little is yet known about the function of *D. melanogaster* glutactin (Olson *et al.*, 1990; Parker *et al.*, 1995; Darboux *et al.*, 1996; Grisaru *et al.*, 1999) and, as noted above, there are no known vertebrate orthologs to offer clues as to its function. The *D. melanogaster* protein is strongly anionic and heavily glycosylated. It is found in many basement membrane sites and is therefore inferred to be a component of the extracellular matrix. It is particularly abundant in the envelope of the CNS, so it fits the recurring theme of a nervous system cell surface adhesive protein seen above for AChE and the other noncatalytic members of the family. Nothing is known about possible ligands.

5.10.4.2. Juvenile Hormone Esterases

Juvenile hormone esterase (JHE) is one of the few insect esterases other than AChE to have a clearly defined physiological substrate. However, known insect JHEs fall into two distinct clades in the phylogeny in **Figure 2**. Known nonlepidopteran JHEs are found in a sister clade to the β-esterases (see Section 5.10.4.3), while known lepidopteran JHEs sit in a more distantly related radiation.

Juvenile hormones (JHs) are a family of sesquiterpenoid esters of methanol found throughout the Insecta (**Figure 7**). The ester moiety is stabilized by conjugation with a 2,3 double bond and it may be this feature of the substrate that requires a specific enzyme (Hammock, 1985). Hydrolysis of the conjugated methyl ester by JHE is traditionally regarded as inactivating the hormone, although mounting evidence suggests that the resultant JH acid also has a hormonal role in some circumstances, with or without re-esterification by a methyltransferase (Sparagana *et al.*, 1985; Ismail *et al.*, 1998, 2000). The most common form of JH is JHIII, which is found in all insect orders that have been investigated (Gilbert *et al.*, 2000). Other forms of JH have the same length of acid chain and generally also the 10(R),11 epoxide group. They differ principally in having various combinations of ethyl rather than methyl substituents on the acid chain (JH0, JHI, JHII), or by an additional 6,7 epoxide group (JHIII bisepoxide, JHB3). Some insects, notably the Lepidoptera and higher Diptera, may use mixtures of JHs, and the JH function may extend to other closely related compounds such as methyl farnesoate (JHIII without the epoxide) (Gilbert *et al.*, 2000).

JH has key roles in the regulation of insect development, metamorphosis, and reproduction (reviews: Gupta, 1990; Riddiford, 1996; Gilbert *et al.*, 2000; Truman and Riddiford, 2002). Certain developmental events require low JH titers and these often coincide with sharp peaks of JHE activity, suggesting that the role of JHE is to substantively clear the insect of JH (de Kort and Granger, 1981, 1996; Hammock, 1985; Roe and Venkatesh, 1990; Gilbert *et al.*, 2000). Some precisely timed experiments have shown peaks of JHE slightly after the JH titer had dropped, suggesting that the role of JHE could be to scavenge for traces of JH remaining after it has mostly

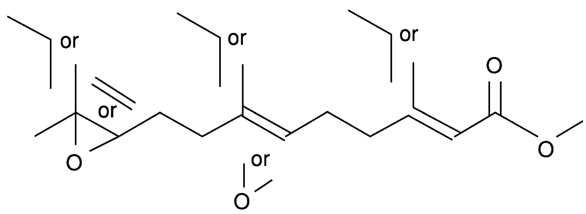

Figure 7 Juvenile hormone (JH) structures. The most common juvenile hormone (JHIII) is shown centrally. Other forms of JH have very similar structures. For example, JHIII bisepoxide has a second epoxide ring replacing the 6,7 double bond of JHIII while methylfarnesoate differs from JHIII by having a double bond in place of the 10,11 epoxide. These three forms of JH may act as a hormone blend in the higher Diptera (Yin *et al.*, 1995). Further forms of JH found particularly in Lepidoptera differ from JHIII by having ethyl side chains replacing one or more of the methyl side chains of JHIII (on C11 for JHII, on C11 and C7 for JHI, and on C11, C7, and C4 for JH0).

been removed by other means, for example, by JH epoxide hydrolases (Baker *et al.*, 1987).

Genetic variation in JHE activity can lead to differences in JH titer, which in turn can have profound effects on development. For example, such variation acts as a genetic switch between short-winged, sedentary and long-winged, migratory forms of some crickets (Zera and Huang, 1999; Zera and Harshman, 2001). Further evidence for a morphogenic role of JHE comes from the disruption of morphogenesis by application of more-or-less specific inhibitors of JHE or interfering RNAs that down-regulate JHE titers (Hajos *et al.*, 1999). The use of the interfering RNAs in final instars of the tobacco budworm *Heliothis virescens* led to aberrant morphogenesis, with the body organization remaining larvalike while the cuticle became pupalike.

The defining characteristics of a JH-specific esterase are a very high affinity for the hormone (typically a 20–200 nM K_m) combined with moderate turnover (k_{cat} of 0.6–4.3 s^{-1}), yielding specificity constants ($6–50 \times 10^6\ M^{-1}\ s^{-1}$) approaching the diffusion limits (Zera *et al.*, 2002; Kamita *et al.*, 2003). This should be sufficient to provide efficient hydrolysis of realistic *in vivo* concentrations of the hormone (Hammock, 1985). At the same time it makes an interesting contrast with AChE (see Section 5.10.3.1), which has an even higher specificity constant for its substrate but achieves this through a very high turnover and only modest K_m.

Most *Jhe* genes have been isolated by the classical reverse-genetics route in which protein purification and amino acid sequencing have then allowed the design of suitable polymerase chain reaction (PCR) primers or probes. Of particular importance has been a trifluoromethylketone affinity technique used for the purification of various leptidopteran JHEs and a coleopteran JHE (Hinton and Hammock, 2003). However, this method has generally proven difficult when applied to nonlepidopteran JHEs, due to either poor binding to the ligand or poor stability during extensive dialysis steps (Campbell *et al.*, 1998b; Zera *et al.*, 2002), although Campbell *et al.* (2001) achieved good recovery of *D. melanogaster* JHE activity when a carrier protein was added. JHE from the cricket *Gryllus assimilis* is the only example of purification from a hemimetabolous insect and its N-terminal sequence has been used to isolate part of the cognate gene (Zera *et al.*, 2002).

The identification of the *Jhe* gene of *D. melanogaster* became possible when the genome of that species was completely sequenced. This was done by matching a peptide mass fingerprint from the purified protein with a predicted gene sequence in the genome sequence (Campbell *et al.*, 2001). It was then possible to identify an orthologous gene from *A. gambiae* once the genome of that species became available (**Figure 2**) (Ranson *et al.*, 2002), although it remains to be demonstrated directly that the latter encodes a functional JHE.

The availability of complete sequences of insect genomes allows us to address an outstanding question from the classical studies on JHE. Do insects have more than one *Jhe*/JHE gene/enzyme system? Multiple JHE activities with different isoelectric points or other physical differences are sometimes found in one species (Khlebodarova *et al.*, 1996; Zera *et al.*, 2002 and references therein). It is generally not clear whether the different JHEs are the products of different genes, differently processed products of the same gene, or allelic variants. Also, it is possible for an esterase to show some JHE activity *in vitro* without evidence for an *in vivo* role in JH metabolism (Campbell *et al.*, 1998b). No study has clearly shown more than one *Jhe* gene in any particular species, although Hinton and Hammock (2003) had evidence for two products from one *Jhe* gene. Nevertheless it is plausible that an insect might use different *Jhe*/JHE systems in different locations (say in tissues and in circulation) or with specificity for different forms of JH. The latter is particularly plausible in the Diptera and Lepidoptera where endogenous forms of JH might act as mixtures of components, which differ in potency in assays, binding affinity to carriers, or relative abundance at different developmental stages (Yin *et al.*, 1995; Gilbert *et al.*, 2000).

The complete genome of *A. gambiae* shows a clade of five esterase sequences that are monophyletic with a pair of esterase sequences in *D. melanogaster*, one of which is the identified JHE (**Figure 2**). The closest relative of these seven dipteran sequences is the identified JHE of a coleopteran, the yellow mealworm *Tenebrio molitor* (Hinton and Hammock, 2003). Thus it seems probable that these eight sequences descend from an ancestral JHE. However, it is also quite possible that some of them no longer function in JH metabolism. Only the *A. gambiae* sequence most closely related to *D. melanogaster* JHE shows the GQSAG version of the GXSXG nucleophilic elbow motif associated with verified JHEs (see below). The second *D. melanogaster* sequence is clearly a duplication of the identified JHE and is adjacent on the chromosome but it also lacks the GQSAG motif. Perhaps one gene in each dipteran has retained the ancestral JHE function, while one duplicated gene in *D. melanogaster* and four in *A. gambiae* have evolved to other functions.

The lepidopteran JHEs form a distinct clade from the dipteran and coleopteran JHEs yet they share the

GQSAG motif. Falling between these two clades are the β-esterases (see Section 5.10.4.3). However, the β-esterase sequences lack the GQSAG motif, there is no physiological evidence suggesting that they might function as JHEs, and one, EST6, has been purified and shown to lack JHE activity *in vitro* (Myers *et al.*, 1993). This suggests that perhaps a single ancestral JHE whose origin predates the separation of several insect orders has subsequently given rise to a non-JHE radiation. Alternatively, the JHE function could have evolved twice in distinct esterase radiations subsequent to the separation of these orders. Interestingly, the lepidopteran JHE clade also includes four *A. gambiae* genes but no *D. melanogaster* genes. This again raises the possibility of multiple JHEs, although none of the four *A. gambiae* genes contains the GQSAG motif that is present in all the lepidopteran JHEs. It also suggests a loss of these genes in the higher Diptera.

Further evidence suggesting multiple JHEs or JHEs diverging to other roles is an unusual protein decribed as "JHE-related" from the cabbage looper *Trichoplusia ni* (Kadono-Okuda *et al.*, 2000). Although this sequence (70 in **Figure 2**) falls within the lepidopteran JHE clade, *T. ni* has another JHE that more closely resembles other lepidopteran JHEs. The JHE-related enzyme hydrolyzes JHIII but its affinity is fourfold less than the more typical JHE from *T. ni* hemolymph. The enzyme shows much lower sensitivity to certain inhibitors and a different expression pattern from classical lepidopteran JHEs. Kadono-Okuda *et al.* (2000) suggest that its function might not be to hydrolyze JH but instead to break down some other, as yet unknown, JH-like compound.

Even more atypical are two putative JHE sequences isolated from *L. decemlineata* (Vermunt *et al.*, 1998). These show only about 17% identity with the JHEs described above and lack the GXSXG nucleophilic elbow motif around the catalytic serine that is characteristic of all known carboxylesterases. Alternatively, these sequences show 29% identity with a bacterial protein that shows oral toxicity against several mosquito species and one lepidopteran (Duchaud *et al.*, 2003). These results could imply an entirely unrelated group of JHE enzymes. Importantly, however, there is as yet no direct demonstration that these genes express JHE activity.

While presence of the above-mentioned GQSAG motif is strongly correlated with JHE sequences, it is not diagnostic for JHEs. The consensus nucleophilic elbow sequence around the catalytic serine residue of all carboxyl/cholinesterases is GXSXG, the first X being most often Glu and the second most often Ala. Gln in the first X position is rare overall but present in all the confidently identified JHEs (Campbell *et al.*, 2001; Hinton and Hammock, 2003). Thomas *et al.* (1999) modeled the structure of a lepidopteran JHE on the known tertiary structures of an AChE and a lipase, and proposed that Gln rather than Glu at this position indirectly shortens the hydrogen bond between the His and Glu residues of the catalytic triad. This might partially account for the very low K_m values of JHEs for their substrates. Aside from the known JHEs and the probable *A. gambiae* JHE, a Gln at this position in an active carboxyl/cholinesterase only occurs twice in the *A. gambiae* genome (14 and 15 in **Figure 2**) and once in the *D. melanogaster* genome (82). The above-mentioned *T. ni* JHE-related enzyme has GQSCG, with the Gln in common with the other JHEs but the Cys residue otherwise unique in the phylogeny.

A second structural feature associated with JHEs is a predicted amphipathic helix with basic residues along one face, first identified in the lepidopteran JHEs (Thomas *et al.*, 1999) and also predicted for *D. melanogaster* JHE (Lys184, Arg191, Arg195) (Campbell *et al.*, 2001). The basic residues form a positively charged patch on the opposite surface of the protein from the active site gorge. This patch might function in the recognition of JHE by specific cells that take up and then degrade the enzyme, thereby contributing to the regulation of its titer in hemolymph (Thomas *et al.*, 1999). This feature is strongly associated with both the lepidopteran and nonlepidopteran JHE clades but seldom seen in otherwise apparently catalytically competent enzymes elsewhere in the phylogeny. Outside the JHE clades there is a trend for substitutions (numbered as per DmJHE) of the second (Arg191) and third (Arg195) basic residues in the face of the amphipathic helix with Gln or the acidic Glu or Asp residues, while the first (Lys184) is generally conserved among clades A to D but not elsewhere.

Beyond the two sequence motifs mentioned above, JHEs must have specific residues that interact with JH molecules to confer their very low K_m values and high specificities. An homology-based model of the tertiary structure of the lepidopteran *H. virescens* JHE could only dock JH in the active site with its orientation reversed relative to acetylcholine in AChE, such that the small alcohol moiety of JH was accommodated by the region homologous to the smaller "acyl binding pocket" while the longer acyl group was accommodated by the larger "anionic site" (Thomas *et al.*, 1999). Activity series with artificial substrates and inhibitors are generally consistent with this reversed-orientation hypothesis (Kamita *et al.*, 2003). Studies with JH analogs show that almost any departure from the JH structure

reduces binding (Campbell *et al.*, 1998b). Consistent with that observation, the *H. virescens* JHE model has JH making contacts with eight further residues (given below in HvJHE numbering) in addition to the residues of the catalytic triad (Thomas *et al.*, 1999). Two (Gly123, Gly124) are the generally conserved oxyanion hole residues. A further two (Pro295 and Phe127) occur often in the alignment. One (Ile449) is unusual but consistent with the generally small residues found adjacent to the His448 of the catalytic triad. The remaining three putative contact residues (Val75, Tyr77, and Phe338) show good conservation among the lepidopteran JHEs but no further and in particular they are not conserved among the nonlepidopteran JHEs. Instead they fall in regions of difficult alignment and indels in the overall esterase alignment (**Figure 6**), as one might expect if these are the regions that confer specificity for diverse substrates.

Much of the above speculation on JHE structure/function may soon be resolved. Kamita *et al.* (2003) announced the crystallization of JHE from the tobacco hornworm *Manduca sexta* with a JH analog, 3-octylthio-1,1,1-trifluoro-2-propanone (OTFP), and expect a high resolution structure to follow soon.

Jhe has attracted significant interest over several years as a potential transgene for insertion into recombinant insect baculoviruses (Hammock *et al.*, 1990) (see **Chapter 6.9**). The objective has been to make the viruses commercially viable prospects as biological insecticides. A range of possible anti-JH effects might follow from an excess of virus-expressed JHE, which could be more effective than the JH-like effects of the chemical "juvenoid" insecticides. In larvae JH is a feeding stimulant so it was hoped that excess JHE would cause larvae to cease feeding while leaving the animals alive to allow further replication of the virus. Alternatively, an anti-JH effect at the time of a larval moult might have caused a precocious and fatal pupal molt.

In the first experiments with baculoviruses expressing wild-type HvJHE, first instar lepidopteran larvae were killed but older larvae were found to rapidly degrade the excess JHE (Hammock *et al.*, 1993; Bonning and Hammock, 1996). It appeared that the levels of circulating JHE were tightly regulated by specific uptake and degradation in pericardial cells. More recent work has therefore attempted to increase the efficacy of this JHE with mutations intended to interfere with its targeting for degradation, thereby allowing a greater increase of JHE activity in the insect (van Meer *et al.*, 2000; Shanmugavelu *et al.*, 2000 and references therein). When Lys29 and Lys524 in this JHE (not those in the amphipathic helix above) were replaced with arginine residues there was no reduction in the clearance of JHE from the hemolymph. However, less JHE was found in the lysosomes of pericardial cells, indicating that intracellular processing of the JHE taken up by the pericardial cells had been effected as intended. There was also less binding to a putative JHE binding protein and this correlated with improved insecticidal efficiency and reduced feeding damage and 17% of larvae showed contractile paralysis.

Curiously, more success was obtained with another mutation, which was actually expected to serve as a negative control. This mutation inactivated the enzyme by substituting a glycine for the catalytic serine residue. Viruses expressing this inactive enzyme killed the larvae more rapidly than did viruses expressing wild-type JHE and they also reduced larval feeding significantly. Some larvae (27%) died at the larval molt with extreme blackening of the cuticle. The remainder showed similar symptoms to larvae infected with the wild-type virus except that some also showed contractile paralysis. These pathologies differ from those seen with the first set of mutants, suggesting different mechanisms of action, but the mutations were not synergistic when combined in the same molecule (van Meer *et al.*, 2000). Enzyme-inactivating mutations of the other two residues of the catalytic triad resulted in viruses that were no more effective than the wild-type. There remains no satisfactory explanation for these results; at face value they could imply a non-catalytic function for the JHE used in these experiments. At the least they serve as dramatic reminders that the functions of JHEs and JHE-like enzymes are still very incompletely understood.

5.10.4.3. β-Esterases

This intensively studied clade (E) is the sister group to the nonlepidopteran JHEs. It comprises two subclades, each with *D. melanogaster* and *A. gambiae* representatives. One contains the so-called β-esterase cluster of *Drosophila*, and the other contains the hemipteran esterases implicated in metabolic resistance to OPs and some other insecticides.

5.10.4.3.1. The *Drosophila* β-esterase cluster The β-esterase cluster was so named by Korochkin *et al.* (1987) because it includes the major esterase isozymes apparent in PAGE analysis of whole organism homogenates of most *Drosophila* species using β-naphthyl acetate as a substrate. As outlined below (see Section 5.10.5.2), those authors also named another, α-esterase cluster, on the basis that it included the major esterase isozymes evident after staining PAGE gels using the isomeric α-naphthyl acetate as

substrate. In fact there are esterases that are polymorphic for α- and β-naphthyl acetate preferring forms (Zouros and van Delden, 1982), so the substrate preference does not necessarily indicate substantial sequence divergence. Nevertheless the names for the two clusters are now widely used and, with the caveat that there is imperfect correspondence with the substrate preference, the usage is retained here.

The β-esterase cluster has been characterized at a molecular and/or biochemical genetic level in many *Drosophila* species, mainly located in four species groups, covering both the subgenera *Sophophora* and *Drosophila* (reviews: Oakeshott *et al.*, 1990, 1993, 1995, 1999). In most species studied it contains two to four members arranged in a tightly linked cluster, with one member being an abundant hemolymph enzyme, another located in late larval integument and, in some cases, one being heavily expressed in male reproductive tissue (**Figure 8**). However, the roles of the different β-esterases in carrying out these functions vary greatly both among and within the species groups.

In the *melanogaster* species group in the subgenus *Sophophora*, the cluster comprises just two very tightly linked, tandemly arranged genes (Oakeshott *et al.*, 1995). In the ancestral state for this species group, as seen in *D. yakuba* and *D. erecta*, the upstream gene, *esterase6* (*Est6*), encodes a homodimer expressed mainly in the hemolymph of most life stages, while the product of the downstream gene, *esterase7* (*Est7*), also a homodimer, is essentially only seen in late larval integument (Dumancic *et al.*, 1997; Oakeshott *et al.*, 2001) (although EST analyses also reveal a brief pulse of expression in early embryos) (http://flygenome.yale.edu/Lifecycle/; see also Arbeitman *et al.*, 2002). However in the derived state, as seen in *D. melanogaster*, *D. simulans*, and *D. mauritiana*, all in the *melanogaster* subgroup of species, EST6 has become a monomer and acquired a major pulse of expression in the anterior sperm ejaculatory duct of the adult male (albeit still retaining strong hemolymph activity) (Oakeshott *et al.*, 2001). Furthermore, *D. melanogaster* at least shows a high frequency of null alleles of the *Est7* gene and it is postulated that it is becoming a functionless pseudogene in this species (Balakirev *et al.*, 2003).

Although little is known about the functional role of the ancestral hemolymph activity of EST6, there is abundant evidence that the acquired ejaculatory duct expression of EST6 in the melanogaster subgroup is important in reproductive biology (Meikle *et al.*, 1990; Richmond *et al.*, 1990). In these species the enzyme is transferred from the male to the female in the semen during mating. Most of it is not then retained in her reproductive tissue but rapidly translocated to her hemolymph, where traces of it survive for several days. It has also been suggested that the evolutionary shift of the enzyme to monomeric structure in the *melanogaster* subgroup has been to facilitate transport of this enzyme across the vaginal wall (Oakeshott *et al.*, 1995). How the male-donated enzyme in the female hemolymph impacts on the role of the female-produced EST6

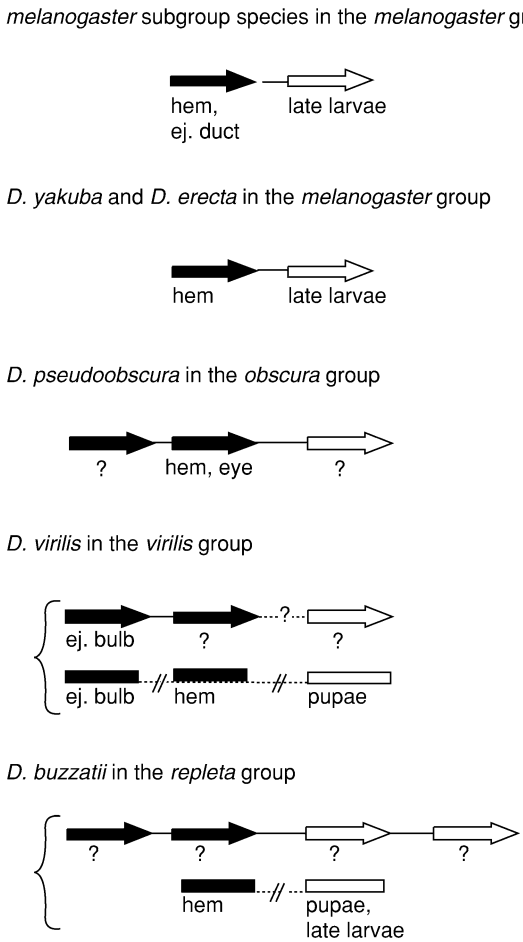

Figure 8 Organization of the β-esterase clusters in various *Drosophila* species as inferred from molecular and classical genetics (arrows and blocks respectively). *Est6* and its putative orthologs are shown in black, *Est7* and its putative orthologs are unshaded. For the molecular data, the arrows indicate directions of transcription. Major expression phenotypes are indicated below the arrows. Question marks indicate unknown linkage and orientation (between the arrows) or unknown expression (below the arrows). ····//··· indicates close linkage but precise relationship unknown. Hem, hemolymph; ej. duct, ejaculatory duct; ej. bulb, ejaculatory bulb. (Adapted from Oakeshott, J.G., Boyce, T.M., Russell, R.J., Healy, M.J., **1995**. Molecular insights into the evolution of an enzyme: esterase 6 in *Drosophila*. *Trends Ecol. Evol.* *10*, 103–110; and Oakeshott, J.G., Claudianos, C., Russell, R.J., Robin, G.C., **1999**. Carboxyl/cholinesterases: a case study of the evolution of a successful multigene family. *BioEssays* *21*, 1031–1042.)

in her hemolymph is a mystery. However, elegant experiments reviewed in Richmond *et al.* (1990) comparing females mated to males bearing wild-type versus laboratory null alleles of *Est6* have shown clear consequences of the transfer of active enzyme for the female's subsequent reproductive behavior. In general terms there is a stimulation of egg laying behavior and an inhibition of receptivity to remating. There are separable short (<24 h) and long (5–7 days) term effects on receptivity. Interestingly some similar effects have also been described for several small peptides found in the semen but there is no evidence as to whether or how the EST6 and small peptide effects are related (Chapman *et al.*, 2003; Liu and Kubli, 2003). EST6 shows activity against a broad range of substrates *in vitro*, plus some limited peptidase/amidase activity, but its *in vivo* substrate(s) is (are) unknown (Richmond *et al.*, 1990).

The localization of EST7 activity to the integument of late larvae/prepupae suggests a fairly specific function during this major metamorphic transition. Alternatively, the high frequency of null alleles in *D. melanogaster* suggests that the function is dispensable, without significant effects on fitness in this species at least.

Detailed comparative genomic analyses have given us some strong clues as to the genetic basis of the acquired reproductive tract expression of EST6 in the *melanogaster* subgroup of species. It appears that the first step was the insertion of a complex macrotransposon into the distal portion of the ancestral *Est6* promoter (Oakeshott *et al.*, 2001; C.W. Coppin, B.C. Morrish, and J.G. Oakeshott, unpublished data). This insertion created a rudimentary promoter element directing ejaculatory duct expression. There was then a burst of nucleotide change in and around this element to hone its function, plus another pulse of change in the *Est6* coding region to adapt the protein to its new function. About 10% of the residues in the protein changed in a period of only 2–6 million years, and many of the changes were clustered in regions that would correspond to the peripheral substrate binding sites of AChE and an inferred ancestral dimerization site.

There is also evidence for functional effects of polymorphic variation in the *Est6* promoter and coding region within *D. melanogaster*. Most populations of the species segregate for two haplotypic forms of the promoter, the two forms differing at 13 sites spread over a ~400 bp region encompassing the introduced ejaculatory duct motifs (Odgers *et al.*, 1995). One of these two forms directs two- to three-fold more expression of the gene in the ejaculatory duct than the other (Odgers *et al.*, 2002). In the laboratory at least, such differences in the males are associated with quantitative differences in the egg laying profiles and remating behaviors of their mates (Saad *et al.*, 1994). There is no direct evidence as to whether these effects carry over to field populations but there is strong evidence from statistical tests of frequency distributions that these haplotype differences are not selectively equivalent in the field (Balakirev *et al.*, 2002; Odgers *et al.*, 2002). Most field populations of *D. melanogaster* are also polymorphic for two amino acid differences in the region of the EST6 protein corresponding to the peripheral substrate binding sites of AChE (Cooke and Oakeshott, 1989). There are kinetic differences between the corresponding allozymes for artificial substrates (White *et al.*, 1988), although the biological significance of these is unclear, either in the laboratory or in the field. Again, however, there is clear evidence that the allozymes are not selectively equivalent in the field. In this case there are large-scale latitudinal clines in their respective frequencies that recur across continents and take complementary forms in the northern and southern hemispheres (Anderson and Oakeshott, 1984).

The other lineage of the subgenus *Sophophora* in which the β-esterase cluster has been well characterized is the *obscura* species group, specifically *D. pseudoobscura* (Brady *et al.*, 1990; Brady and Richmond, 1990, 1992). In this species the cluster comprises three genes (**Figure 8**). The 3′ gene, termed *Est5C*, is orthologous to the 3′ gene (*Est7*) in the *melanogaster* cluster, while the two upstream genes, *Est5A* and *Est5B* (the latter sometimes just termed *Est5*), are duplicates of their common ancestor with *Est6* in the *melanogaster* cluster. The EST5 protein shows the high hemolymph activity seen for EST6 in the *melanogaster* group, albeit EST5 also shows high activity of unknown physiological significance in the eye. Nothing is known of the physiological roles of EST5A and EST5C, although their sequences show all the motifs expected for catalytic activity. Interestingly, some allozymes of EST5 differ in monomer/dimer status, suggesting that the ancestral dimeric status can be abolished by one or a very few amino acid differences (Arnason and Chambers, 1987).

Albeit less thoroughly characterized, it is clear that the β-esterase cluster in the subgenus *Drosophila* has diverged substantially from those outlined above for the two sophophoran species groups (**Figure 8**). Classical genetic analyses show a cluster of three genes encoding catalytically active β-esterases in *D. virilis*, in the *virilis* species group (Korochkin *et al.*, 1987, 1990). One of these, termed EST2, is

abundant in the hemolymph while another, ESTS, is abundant in the male reproductive tract. Unlike EST6, ESTS is produced in the ejaculatory bulb, not the duct, and, although transferred to the female, it is not transferred to hemolymph, but retained in the vagina. There are in fact reports of seminal fluid esterases that are retained in the vagina in various insects (Mikhailov and Torrado, 2000). Some of these have also been implicated in egg laying and remating behavior, with the mechanism suggested to involve the digestion of waxy matrices, which otherwise retain yet-to-be-used sperm in their sperm storage organs (Korochkin *et al*., 1976). This mechanism has been proposed to apply to *D. virilis*, in which mated females have a waxy plug at their entrance of their sperm storage organ whereas, notably, mated *D. melanogaster* females do not (Korochkin *et al*., 1976; Oakeshott *et al*., 1990; Healy *et al*., 1991).

Molecular work has also revealed a cluster of three β-esterase genes in *D. virilis* (Enikolopov *et al*., 1989; Korochkin *et al*., 1990, 1995; Sergeev *et al*., 1993, 1995) which map cytologically to the region where the classical genetics locates the three β-esterase isozyme loci. One of the cloned genes is heavily expressed in the ejaculatory bulb and was, therefore, originally nominated as the *EstS* gene. However, the sequence of the encoded protein shows a nonconservative substitution of the histidine in the catalytic triad which would almost certainly inactivate it. While it is tempting to put this down to a sequencing error, in fact (below) a parallel situation in the β-esterase cluster of *D. buzzatii*, in the *repleta* species group is seen. The alternative is to suggest that ESTS and perhaps also the other two β-esterase isozymes are encoded by as yet uncloned gene(s) at nearby chromosomal location(s). The corollary of this is that both an active and a catalytically inactive β-esterase are highly expressed in the ejaculatory bulb. Its abundant expression might suggest a function for the inactive protein, and as seen in the earlier sections there are many catalytically inactive carboxyl/cholinesterases, which have important ligand-binding functions. The *D. virilis* β-esterases clearly warrant further genetic and biochemical analyses.

Classical genetic analysis of *D. mojavensis* in the *repleta* species group shows a cluster of two β-esterase isozymes, one expressed in hemolymph and the other in late larvae (Zouros *et al*., 1982; Zouros and van Delden, 1982) and, although not mapped genetically, there is also evidence from several *repleta* species for a third β-esterase, which is highly expressed in male reproductive tissue (Kambysellis *et al*., 1968; Oakeshott *et al*., 1990). Molecular analysis of *D. buzzatii* in this species group has identified a cluster of three carboxyl/cholinesterase genes, which sequence similarities suggest should be its β-esterase cluster (East *et al*., 1990; Gomez and Hasson, 2003). However, the sequences of two of these show a glycine in place of the catalytic serine, which would clearly render them catalytically inactive. Given that *D. buzzatii* does express active hemolymph and late larval β-esterases (East *et al*., 1990), it appears that there may be two clusters of β-esterase or like genes in this species. And as with *D. virilis*, one of them appears to encode noncatalytic products.

The *A. gambiae* genome has a four-gene cluster which is clearly the sister group for the *Drosophila* β-esterase cluster (**Figure 2**). All four genes appear to encode catalytically active enzymes but there appears to be no information on their expression profiles. Several esterase isozymes are expressed in hemolymph and male reproductive tract in this species and other anophelines, but their relationship to the sequences in question is uncertain (Narang and Seawright, 1982; Vernick *et al*., 1988).

5.10.4.3.2. Amplified hemipteran β-esterases Also in part of the β-esterase clade (E) are a group of secreted esterases (which would actually be classified as α-esterases on the basis of their α/β-naphthyl acetate preferences) whose overexpression provides a major mechanism of resistance to OPs and carbamates in several hemipterans.

In *M. persicae* metabolic resistance to these insecticides is associated with a marked increase in total carboxylesterase activity (Needham and Sawicki, 1971). Four phenotypic classes have been identified; susceptible, moderately resistant (R1), highly resistant (R2), and extremely resistant (R3). Variously elevated levels of esterase activity are found in all three resistant classes, due to overexpression of either of two esterase isozymes, E4 and FE4 (Devonshire and Sawicki, 1979; Field *et al*., 1988, 1993). In some resistant lines the levels of the esterase protein reach 10 pM enzyme per aphid, or approximately 1% of the total soluble protein (Devonshire, 1989). The two enzymes differ slightly in molecular weight (E4 65 kDa, FE4 66 kDa) and they have slightly different catalytic activities. The genes encoding these enzymes are closely related (98% amino acid identity), genetically linked (19 kb apart), and likely to be recently derived by gene duplication (Field and Devonshire, 1998). Flanking sequences also differ between the two genes. The FE4 gene has a 1.7 kb deletion of promoter region compared with E4, resulting in a shorter 5′ untranslated region (94 bp). It is also likely that there are two further esterases

in the region, creating a cluster of at least four esterase genes even in susceptible *M. persicae* (Field and Devonshire, 1998).
